Abstract

The RD52 calorimeter uses the dual-readout principle to detect both electromagnetic and hadronic showers, as well as muons. Scintillation and Čerenkov light provide the two signals which, in combination, allow for superior hadronic performance. In this paper, we report on detailed, GEANT4 based Monte Carlo simulations of the performance of this instrument. The results of these simulations are compared in great detail to measurements that have been carried out and published by the DREAM Collaboration. This comparison makes it possible to understand subtle details of the shower development in this unusual particle detector. It also allows for predictions of the improvement in the performance that may be expected for larger detectors of this type. These studies also revealed some inadequacies in the GEANT4 simulation packages, especially for hadronic showers, but also for the Čerenkov signals from electromagnetic showers.

1 Introduction

Dual-readout calorimetry is a novel particle detection technique, which makes it possible to measure electrons, photons and hadrons with very good precision, and without the (inter-)calibration issues that complicate working with traditional calorimeter systems that consist of separate electromagnetic (em) and hadronic sections. There is a growing interest in applying this technique, both for upgrades of existing detector systems (*e.g.*, the CMS experiment at CERN's Large Hadron Collider) and for experiments at proposed future particle colliders or in space.

Generic prototypes of dual-readout calorimeters have been and are being built by the DREAM and RD52 Collaborations. Test results have been published in a number of papers [1]. The largest detector of this type had an instrumented mass of 1350 kg. This was of course more than enough to study em showers (and also muons) in all possible detail. However, high-energy hadron showers are typically only contained at the 90-95% level in an instrument of this size and, therefore, the ultimate performance for hadron detection could not (yet) be assessed properly. However, the results obtained for the incompletely contained showers are very encouraging.

In this paper, we report on an extensive program of Monte Carlo studies of the performance of these unusual particle detectors. The purpose of these studies was:

- (1) To test the (limits of the) validity of such simulations with experimental data already obtained. In particular, we were interested in the dependence of the response and the energy resolution on parameters such as the particle's energy and its angle of incidence. The simulations also predicted certain effects that had not yet been studied experimentally, such as the anti-correlation between the two types of signals produced by the calorimeter. Verification of these predictions was also important in assessing the validity of the simulations.
- (2) To predict the effects on the performance for certain modifications of the detectors, for example a larger instrumented mass, an increased light yield, or a different choice of absorber medium.

These studies also made us aware of a number of subtle details of shower development and their (observable) consequences in this intricate particle detector. The paper is organized as follows. In Section 2, the structure of the simulated calorimeters and details of the simulation programs are described. Results of the simulations are given in Sections 3, 4 and 5 for muons, electrons and hadrons, respectively. The results are evaluated and discussed in Section 6.

2 Equipment and simulations

The RD52 calorimeters form the second generation of integrated em + hadronic calorimeters based on separate readout of the scintillation and Čerenkov light pro-

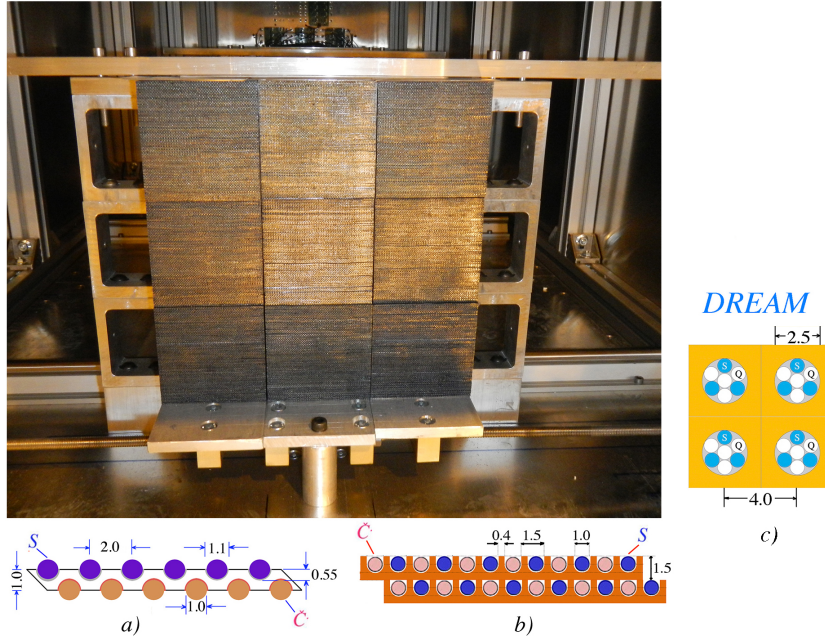

Fig. 1. Front view of the tested SuperDREAM calorimeter, and the basic structure of the lead (a) or copper (b) based modules. For comparison, the structure of the original DREAM calorimeter is shown as well (c). All dimensions are given in mm.

38 duced in the shower development. Two different types of optical fibers are used as
 39 the active media in this detector: Scintillating fibers for the scintillation light and
 40 clear PMMA plastic fibers for the Čerenkov light. In the first generation (called
 41 DREAM), these two types of fibers were housed together in the holes of extruded
 42 copper rods (see Figure 1c). In the RD52 (SuperDREAM) detector, each fiber is
 43 separately embedded, which leads to a substantially larger sampling frequency
 44 and correspondingly reduced sampling fluctuations. Also, the Čerenkov light is
 45 detected in clear plastic fibers, while quartz fibers were used for this purpose in
 46 DREAM.

47 Figure 1 shows a picture of the front face of the RD52 calorimeter. It consists of
 48 nine modules, each module is subdivided into four towers, and each tower generates
 49 two signals, one from the scintillating fibers and one from the Čerenkov ones. In
 50 total, this detector thus produces 72 signals for each event.

51 These particular modules were built with lead as absorber material. Figure 1a shows
 52 a detail of the structure, with alternating layers of scintillating and clear fibers. We
 53 also built several modules using copper as absorber material. The fiber arrange-
 54 ment in these modules, depicted in Figure 1b, was slightly different. Each module
 55 measured $92 \times 92 \text{ mm}^2$ and contained about 4000 fibers, 2000 of each type.

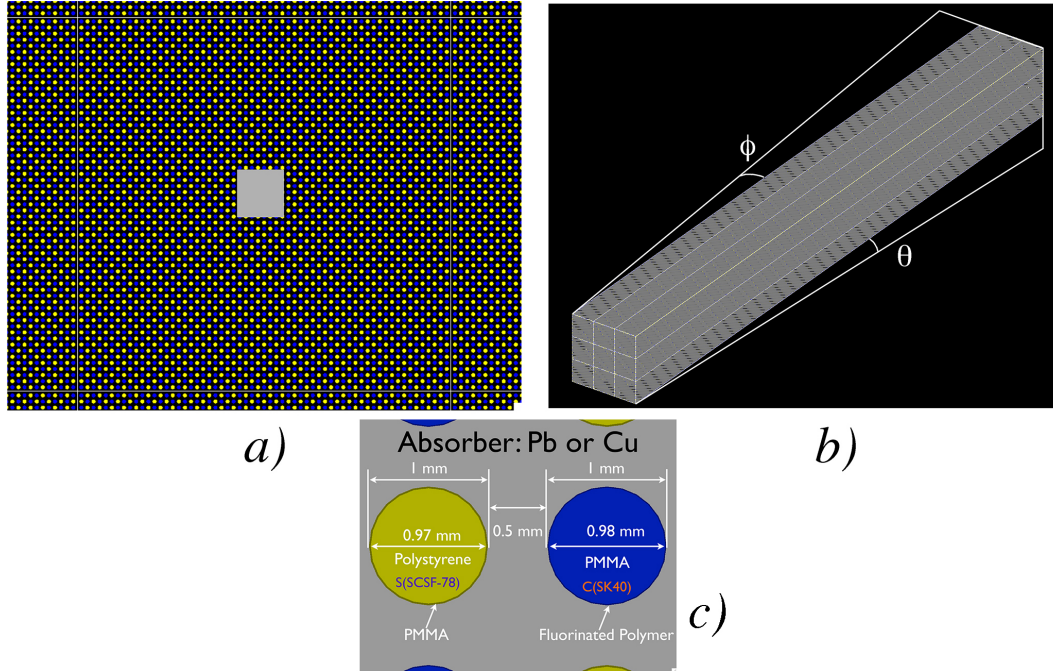

Fig. 2. The simulated calorimeter structure. Shown are part of the front face, including the $10 \times 10 \text{ mm}^2$ beam size used in the simulations (a), the entire calorimeter module oriented at a tilt angle θ and an azimuth angle ϕ with respect to the incident particle beam (b), and a detail of the front face showing the fiber arrangement (c).

56 2.1 The simulated calorimeter structure

57 The simulated calorimeter structure was almost identical to the experimental ones.
 58 It consisted of nine modules, measuring $92 \times 92 \text{ mm}^2$ each. The fibers were dis-
 59 tributed according to a square grid, as shown in Figure 2a,c. Each module contained
 60 3721 fibers. The absorber material could be chosen. In these studies, we used ei-
 61 ther lead or copper. Small differences with the RD52 calorimeters concerned the
 62 fact that no tolerances were applied to the grooves that contain the fibers. Since the
 63 simulated modules thus do not contain any air, the sampling fraction is somewhat
 64 smaller than for the experimental ones. On the other hand, this is compensated by
 65 the fact that light produced anywhere in the 1 mm thick fibers was taken into ac-
 66 count in the simulations. In reality, the cladding of the fibers does not contribute to
 67 the creation of scintillation light. Also, the fiber arrangement was not exactly the
 68 same as in the RD52 calorimeters. In the simulations, a perfectly square grid was
 69 used for both types of fibers, while in reality the arrangement was slightly different.
 70 Yet, the total number of fibers per module was approximately the same in all cases.

71 Figure 2b shows the orientation of the entire, 2.5 m long detector, at an angle with
 72 respect to the beam particles entering the detector through its front face. The angles
 73 θ and ϕ indicate the tilt and the rotation in the horizontal plane, respectively.

74 All simulations described in this paper were carried out for a calorimeter with the
 75 structure described above. However, some of the experimental data with which

76 comparisons are being made were obtained with the DREAM calorimeter, in which
77 the fiber arrangement was quite different (see Figure 1c). This was true for all muon
78 data, and for the hadron data taken with a copper based calorimeter. In order to
79 assess the possible effects of the different calorimeter structure, a subset of the sim-
80 ulations was **also** performed for a calorimeter structure that closely represented the
81 one shown in Figure 1c. The results of this exercise are described in the appendix ².
82 In the same spirit, we have also investigated the possible effects of air gaps inside
83 the calorimeter structure, and the effects of changing the physics list in the simula-
84 tions. The results of this work are also described in the appendix. The figures shown
85 in the following sections were obtained for the calorimeter structure from Figure 2,
86 unless explicitly stated otherwise.

87 2.2 The simulations

88 The simulations were carried out with the GEANT4 Monte Carlo package [2].
89 Events were generated with GEANT4.9.6 patch-02, which was released in May
90 2013. For applications of calorimetry in high energy physics, GEANT4 recom-
91 mends to use the FTFP_BERT physics list which contains the Fritiof model [3],
92 coupled to the Bertini-style cascade model [4] and all standard electromagnetic
93 processes. This is the default physics list used in simulations for the CMS and AT-
94 LAS experiments at CERN’s Large Hadron Collider [5].

95 Each run consisted of typically 3000 events. The impact point of the particles was
96 randomly distributed over a $10 \times 10 \text{ mm}^2$ area around the center of the detector. For
97 the (highly directional) Čerenkov light, each photon was examined and followed
98 all the way as it propagated to the rear end of the detector if it was emitted within
99 the numerical aperture of the fiber. In order to translate the Čerenkov signals into a
100 measured number of photoelectrons, an overall quantum efficiency factor was ap-
101 plied ³. This quantum efficiency depends on a number of factors that change from
102 photon to photon: The photon energy, the angle of incidence, the point of incidence
103 on the photocathode, *etc.* This is impossible to simulate. For that reason, we have
104 chosen to use a fixed number for this quantum efficiency throughout these simu-
105 lations: 0.11. This number is very reasonable, since it reproduces the “light yield”
106 (*i.e.*, the average number of photoelectrons produced per GeV deposited energy,
107 which we measured in several different ways) quite well. Any other choice of this
108 quantum efficiency would *only* have affected the em energy resolution, which is
109 dominated by Poisson fluctuations in the number of photoelectrons, but *none* of the
110 other characteristics of the Čerenkov signals discussed in this paper.

² Since experimental muon data were *only* obtained with the DREAM calorimeter, the ex-
perimental results are in this case compared with the results of these additional simulations
in the text (Section 3).

³ We used the Optical Boundary (OpBoundary) process provided in GEANT for this pur-
pose.

111 The numerical aperture was calculated on the basis of the indices of refraction
 112 provided by the producers of the fibers used in the calorimeters: $n = 1.49$ and 1.42
 113 for the core and cladding materials of the PMMA fibers, $n = 1.458$ and 1.42 for the
 114 core and cladding materials of the quartz fibers used in the DREAM calorimeter.

115 For the scintillation signals, it was not necessary to follow each photon in detail.
 116 Since the scintillation photons are emitted isotropically, the signals were (in first
 117 approximation) proportional to the energy deposited in the scintillating fibers by
 118 the ionizing shower particles. However, there is one important caveat: Saturation of
 119 the light produced by densely ionizing particles. This phenomenon especially af-
 120 fects the hadronic scintillation signals, in particular the contributions from protons
 121 produced in nuclear breakup and neutron scattering. It is described by the following
 122 expression:

$$\frac{dL}{dx} \propto \frac{dE/dx}{1 + k_B \cdot dE/dx} \quad (1)$$

123 where L is the amount of light produced by a particle of energy E and k_B a mate-
 124 rial property known as Birks' constant [6]. This constant is typically of the order
 125 of $0.01 \text{ g cm}^{-2} \text{ MeV}^{-1}$, whereas the specific ionization (dE/dx) of a minimum
 126 ionizing particle mip is of the order of $1 \text{ MeV g}^{-1} \text{ cm}^2$. In comparison with $mips$,
 127 the specific light production (photons per unit energy) is thus reduced by a fac-
 128 tor 2 (11) for particles with a specific ionization of 100 (1000) times the value for
 129 minimum ionizing particles. For the scintillating fibers used in our calorimeters, k_B
 130 was determined to be 0.126 mm/MeV [7], and this is the value we used to convert
 131 deposited energy into scintillation signals in these simulations.

132 2.3 Calibration

133 Just like in the analyses of all the experimental data obtained with the DREAM
 134 and RD52 dual-readout calorimeters, the energy scale in our simulations was de-
 135 termined from the response to 40 GeV electrons, both for the scintillation and the
 136 Čerenkov signals. The angle of incidence of the beam particles was the same for
 137 the calibration and for the electron energy scan, both in the experiment and in the
 138 simulations: $(\theta, \phi) = (1.0^\circ, 1.5^\circ)$. Electrons entering a tower in its center deposit
 139 typically about 85% of their energy in that tower, regardless of their energy. The
 140 establishment of the relationship between deposited energy and the average result-
 141 ing signal (*i.e.*, the calibration constants) is thus straightforward when electrons
 142 are being sent into each calorimeter tower. These calibration constants were sub-
 143 sequently used to determine the energy equivalence of the signals recorded for all
 144 other particles (electrons, hadrons and muons).

145 In the analyses of the experimental data, corrections had to be applied for light at-

146 tenuation in the fibers [8,9]. This was necessary in order to convert the signals from
147 hadrons and muons, which produce light much deeper inside the calorimeter than
148 the electrons that were used for the calibration, to the same energy scale. However,
149 in the simulations this procedure was not necessary, since the signals from these
150 particles are automatically converted to that energy scale by using the calibration
151 constants as derived above. On the other hand, light attenuation corrections in the
152 simulations would be needed if one wanted to compare with raw experimental sig-
153 nal distributions.

154 **3 Results for Muons**

155 Detailed experimental studies of the muon response functions were only carried
156 out with the original DREAM calorimeter [9]. In order to avoid contributions from
157 signals generated in the windows of the PMTs, these studies were performed at an
158 angle of incidence (θ, ϕ) of $(0.7^\circ, 6^\circ)$.

159 The simulations were performed both with the standard (RD52) geometry, and with
160 the actual (DREAM) geometry in which the experimental data were obtained. In
161 Figure 3, the latter simulation results are shown, together with the experimental
162 data⁴.

163 The most interesting experimental result of the muon studies is the fact that the
164 deposited energy, as derived from the observed signals, is not the same for the two
165 types of fibers. As the muon energy increases from 40 to 200 GeV, the average
166 measured energy loss increases substantially, as a result of the increased brems-
167 strahlung losses. However, the energy loss measured with the scintillating fibers is
168 systematically larger than for the clear ones, by a constant amount. The explanation
169 of this remarkable fact is that the clear fibers do not produce a signal from the ion-
170 ization component of the energy loss, since the Čerenkov photons emitted in that
171 process fall outside the numerical aperture of the fibers. The clear fibers thus only
172 register the muon's radiation losses, while the scintillating fibers *in addition* also
173 detect the ionization loss.

174 The results of the GEANT4 simulations, shown in Figure 3, also exhibit a sys-
175 tematic and constant difference between the muon's energy loss derived from the
176 signals in the two types of fibers. However, this difference is somewhat smaller than
177 in reality, mainly because the simulated Čerenkov signals are a bit larger than the
178 measured values. This is also illustrated in Figure 4, where the ratio of the average
179 scintillation and Čerenkov signals is plotted as a function of the muon energy. Just
180 as in the experimental data, the simulated ratio increases with energy, but the value
181 of that ratio is about 20-25% larger than in practice.

⁴ The simulations with the RD52 geometry confirmed the conclusions described in this section. See appendix for details.

Fig. 3. The average measured energy loss by muons in the DREAM copper calorimeter, as a function of the muon energy. The experimentally measured results are compared with the GEANT4 simulated ones. The DREAM calorimeter was calibrated with 40 GeV electrons. The simulations were performed for the actual (DREAM) structure of the calorimeter with which the experimental data were obtained (Figure 1c).

182 4 Results for Electrons

183 4.1 The e/mip ratio

184 An important characteristic of any sampling calorimeter is the so-called e/mip
 185 ratio. This parameter indicates the efficiency with which electromagnetic showers
 186 are sampled, relative to minimum ionizing particles. As we will see, this parameter
 187 depends on the choice of the absorber material and has profound consequences for
 188 some aspects of the calorimeter performance.

189 The efficiency with which $mips$ are sampled follows directly from the structure of
 190 the calorimeter, and the materials of which it is composed. In our case, the cross
 191 section of one simulated module measures $92 \times 92 = 8464 \text{ mm}^2$. It contains 3721
 192 round fibers with a diameter of 1 mm each, for a total cross section of 2922 mm^2 ,
 193 1461 mm^2 for each of the two types of fibers. The remaining 5542 mm^2 is taken by
 194 the absorber material, since no air gaps around the fibers are assumed.

195 The specific energy loss of a mip amounts to 12.73 MeV/cm in lead, vs. 12.57
 196 MeV/cm for copper. For the fibers, the specific energy loss is 2.05 MeV/cm for

Fig. 4. The ratio of the average Čerenkov and scintillation signals from muons traversing the calorimeter, as a function of the muon energy. The experimentally measured results [9] are compared with the GEANT4 simulated ones. The calorimeters were calibrated with 40 GeV electrons, and the simulations were performed for the actual (DREAM) structure of the calorimeter with which the experimental data were obtained (Figure 1c).

197 the (polystyrene) scintillating fibers, and 2.30 MeV/cm for the (PMMA) Čerenkov
 198 ones. This leads to a sampling fraction for *mips* of $(2.05 \times 1461)/(2.05 \times 1461 +$
 199 $2.30 \times 1461 + 12.57 \times 5542) = 3.94\%$ for the copper/scintillating-fiber structure
 200 and 3.89% for the lead/scintillating-fiber one.

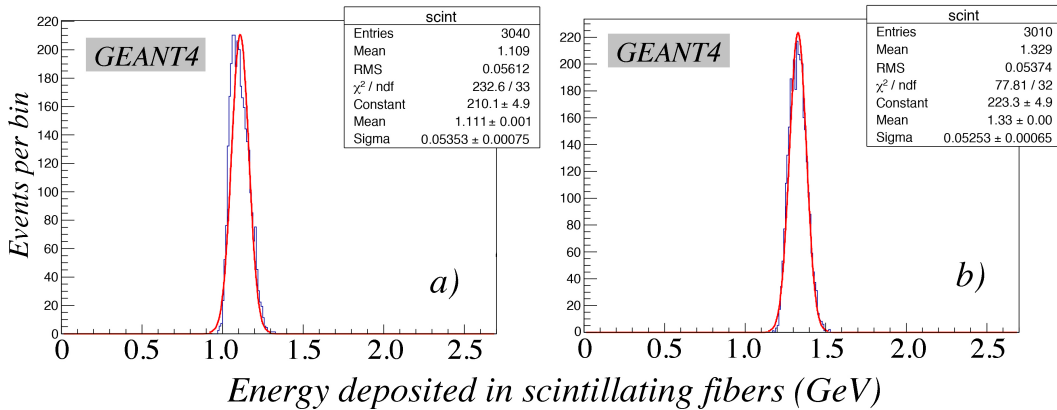

Fig. 5. Distribution of the energy deposited by 40 GeV electrons in the scintillating fibers of the lead (a) and the copper (b) calorimeter structure. The angle of incidence of the electrons (θ, ϕ) was $(1.0^\circ, 1.5^\circ)$ in these GEANT4 simulations.

201 As is shown later in this section, the sampling fraction for electromagnetic showers
 202 is, for all practical purposes, independent of the energy and the angle of incidence

203 of the electrons. Figure 5 shows representative scintillation response functions, for
204 40 GeV electrons in the lead (Figure 5a) and copper (Figure 5b) modules, respec-
205 tively. On average, these electrons deposit 1.109 and 1.329 GeV in the scintillating
206 fibers and, therefore, the sampling fractions for the em showers in these calorime-
207 ters amount to 2.77% (lead) and 3.32% (copper), respectively. And thus we find
208 that the e/mip ratios are 0.71 for the lead/scintillating-fiber calorimeter and 0.84
209 for the copper/scintillating-fiber one.

210 In the early days of calorimetry, it was generally believed that in an em shower,
211 the energy is deposited by a large collection of minimum ionizing particles (elec-
212 trons and positrons), and that therefore the e/mip ratio has to be 1.0. The fact that
213 this was not the case in practice gave rise to a lot of speculations [10–12]. How-
214 ever, the explanation for this phenomenon turned out to be the fact that a large
215 fraction of the shower energy is deposited in the late stages of the shower develop-
216 ment, through processes such as Compton scattering and the photoelectric effect.
217 In a sampling calorimeter, the energy sharing between the different materials is for
218 these processes very different than for minimum ionizing particles traversing the
219 calorimeter. For example, the cross section for photoelectric effect is proportional
220 to Z^5 . This means that in a lead/plastic structure, photoelectrons are in practice
221 only produced in the absorber, and these photoelectrons only contribute to the sig-
222 nal if they are produced sufficiently close to the boundary with a plastic fiber. In
223 practice, the response to the particles produced in the late stages of the shower de-
224 velopment is thus suppressed compared to the response to $mips$. This suppression
225 is larger in calorimeters with high- Z absorber material and in calorimeters with a
226 small sampling frequency (*i.e.*, thick absorber layers) [13].

227 Just like in the early days of EGS3 [14], the Monte Carlo simulations confirm the
228 essential aspects of this explanation. The suppression of the late-stage signals is
229 clearly more important when lead ($Z = 82$) is used as absorber than for copper
230 ($Z = 29$). Yet, the suppression is somewhat less in this fine-sampling structure
231 than in more crudely sampling lead/plastic-scintillator calorimeters such as the one
232 built by members of the ZEUS Collaboration, for which an e/mip value of 0.67
233 was reported [15].

234 One consequence of these results is that the calorimeter signal of the lead calorime-
235 ter is more strongly dominated by the early, highly collimated shower component
236 than that of the copper calorimeter. In the latter, the diffuse rather wide component
237 from particles generated beyond the shower maximum plays a larger role. The ef-
238 fects of this difference manifest themselves, for example, in the quality of a Gaus-
239 sian fit to the response function. Figure 5 shows that the (normalized) χ^2 of this
240 Gaussian fit amounts to 233/33 for lead and 77.8/32 for copper. The explanation of
241 this difference is the topic of the next subsection.

242 4.2 The calorimeter response function for electrons

243 4.2.1 Angular dependence of the scintillator response functions

244 The lateral profile of em showers has several components. Before the shower maxi-
 245 mum, the energy is primarily deposited by energetic e^+e^- pairs that travel in almost
 246 the same direction as the incoming primary electron. Beyond the shower maxi-
 247 mum, electrons from processes such as Compton scattering have a very different,
 248 much broader angular distribution. The RD52 Collaboration has measured the later-
 249 al shower profile for 100 GeV electrons [16], which shows that $\sim 20\%$ of the
 250 shower energy is deposited in an area of 2×2 mm² around the shower axis. Since
 251 the early, collimated shower component is extremely narrow, the calorimeter re-
 252 sponse becomes dependent on the impact point of the electrons when these parti-
 253 cles travel in the same direction as the fibers. An impact point in a scintillating fiber
 254 will lead to a larger scintillation signal than an impact point somewhere in between
 255 scintillating fibers, *i.e.*, in the absorber material or a Čerenkov fiber. This is because
 256 the early, collimated component generates a large signal contribution in that one hit
 257 fiber.

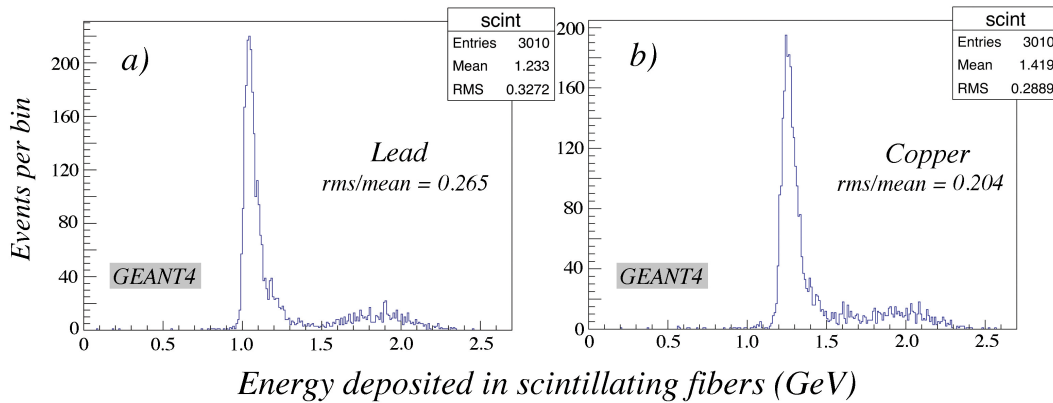

Fig. 6. Distribution of the energy deposited by 40 GeV electrons in the scintillating fibers of the lead (a) and the copper (b) calorimeter structure. The angle of incidence of the electrons (θ, ϕ) was $(0^\circ, 0^\circ)$ in these GEANT4 simulations.

258 Figure 6 shows the effect of this. The response function for 40 GeV electrons consists of two distinctly different components. The broad component represents the events in which the beam particles entered the calorimeter in a scintillating fiber. The signals are in this case larger than those constituting the narrow component, which contains all the other events. It is interesting to compare the response functions for the lead (Figure 6a) and copper (Figure 6b) calorimeters in some detail. Both exhibit the same double-hump structure, but the difference between the mean response values of these two humps is clearly smaller in the case of copper.

266 This can, for example, be concluded from the value of the ratio $rms/mean$ for these distributions: 0.265 for lead, 0.204 for copper. The reason for this difference is the same as the reason for the difference in e/mip values, discussed in the previous subsection. The larger the relative contribution of the late, broad shower component

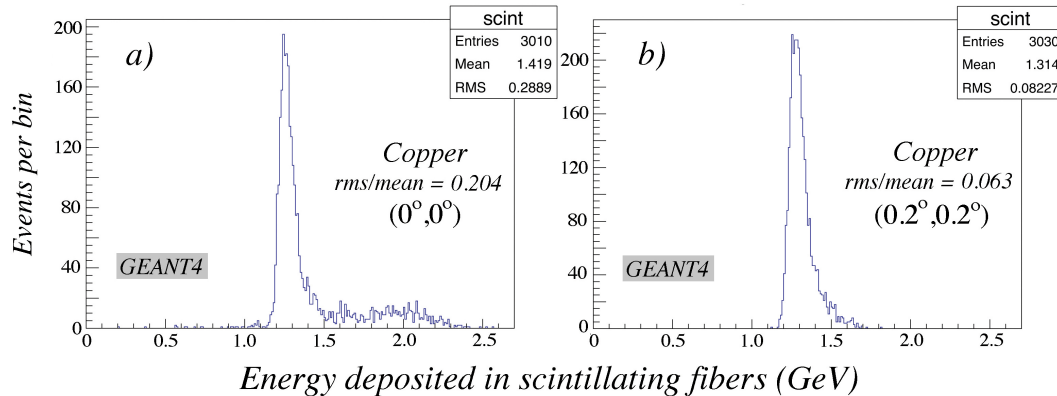

Fig. 7. Distribution of the energy deposited by 40 GeV electrons in the scintillating fibers of the copper calorimeter structure. The angle of incidence of the electrons (θ, ϕ) was $(0^\circ, 0^\circ)$ in diagram *a* and $(0.2^\circ, 0.2^\circ)$ in diagram *b*. Results from GEANT4 simulations.

270 to the calorimeter signal, the smaller the difference between the mean signals from
 271 events where the electron enters the calorimeter in a scintillating fiber or elsewhere,
 272 *i.e.*, the smaller the *rms/mean* value for the total signal distribution.

273 The extreme sensitivity of the calorimeter response to the impact point of the show-
 274 ering electrons exhibited in Figure 6 rapidly decreases when the electrons enter the
 275 calorimeter at a small angle with the fiber direction. In that case, the early, col-
 276 limated shower component does not entirely develop inside a single fiber, but is
 277 increasingly sampled just like the shower particles produced in the later stages.
 278 Since the fibers have a radius of only 0.5 mm, and the radiation length of the cop-
 279 per calorimeter (which sets the scale for the longitudinal shower development) is
 280 about 50 times larger, the angle of incidence for which this becomes a significant
 281 effect is very small indeed.

282 This is illustrated in Figure 7, which shows the effect of rotating the angle of inci-
 283 dence (θ, ϕ) from $(0,0)$ to $(0.2^\circ, 0.2^\circ)$ on the response function of the scintillation
 284 signals from the copper calorimeter. The high-side tail of the response function al-
 285 most completely disappears as a result of this very small rotation. In this process,
 286 which corresponds to tilting and displacing the rear end of the calorimeter module
 287 by only 6 mm, the *rms/mean* value of the scintillator response function is reduced
 288 from 0.204 to 0.063. In fact, the orientation of the calorimeter is so sensitive to the
 289 precise value of (θ, ϕ), that in practice extreme response functions such as those dis-
 290 played in Figure 6 have never been observed in our measurements⁵. Yet, the fact

⁵ It should be pointed out that the angular divergence of the beam particles played no role in this. This divergence was smaller than 0.1 mrad, *i.e.*, more than a factor of 30 smaller than the effect of a rotation from 0 to 0.2° . The fact that extreme response functions such as the one shown in Figure 7a have not been observed in practice is more likely due to the difficulty of precisely orienting the module with respect to the beam line. It may also be a consequence of the fact that the fibers are never perfectly straight, for example because of tolerances in the grooves that contain them.

291 that the em response function of fiber calorimeters substantially broadens when
 292 the angle between the incident particles and the fiber direction approaches zero is
 293 experimentally well established [17].

294 As illustrated by Figure 5, further rotation to angles of the order of 1° leads to a
 295 complete disappearance of the high side tail. Only the relatively poor χ^2 of the
 296 Gaussian fit, especially for the lead calorimeter, is testimony to the effects that
 297 spoil the scintillator response function for angles of incidence very close to zero.
 298 The differences between the lead and copper structures can be understood from the
 299 fact that the radiation length of lead is almost a factor of three smaller than for
 300 copper. As a result, the extremely collimated part of the shower extends much less
 301 in depth, and a small rotation of the calorimeter has a correspondingly smaller effect
 302 on the energy sharing of this component between the active and passive calorimeter
 303 media.

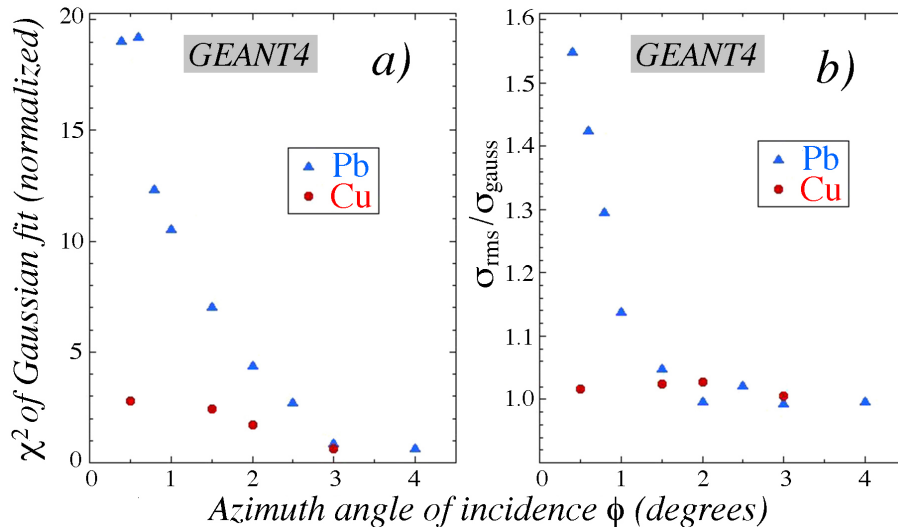

Fig. 8. The normalized χ^2 of a Gaussian fit (χ^2/ndf) to the response function (a) and the ratio of the *rms* width and the σ of a Gaussian fit (b) as a function of the azimuth angle of incidence ϕ of the 40 GeV electrons. The tilt angle θ was chosen to be 1° in all simulations. Results are given separately for these GEANT4 simulations of em shower development in the lead and copper/scintillating-fiber structures.

304 Figure 8 shows how the quality of a Gaussian fit to the scintillator response function
 305 improves as the angle is increased. Results are given separately for the lead and
 306 copper structures. When the angle θ reaches values of 2-3°, the response function
 307 is in very good approximation Gaussian, even for lead.

308 4.2.2 Comparison of the scintillator and Čerenkov response functions

309 We now turn our attention to the Čerenkov response function. Experimentally, we
 310 have observed that the deviations from a Gaussian shape that characterize the scin-
 311 tillator response function for very small angles of incidence are practically absent

312 for the Čerenkov signals [16,8], especially in copper. The Monte Carlo simulations
 313 confirmed this phenomenon, as illustrated in Figure 9, which shows the simulated
 314 response functions for 40 GeV electrons in the scintillation and Čerenkov channels
 315 for a lead calorimeter oriented at $(1^\circ, 1^\circ)$ and a copper one oriented at $(0.4^\circ, 0.4^\circ)$.

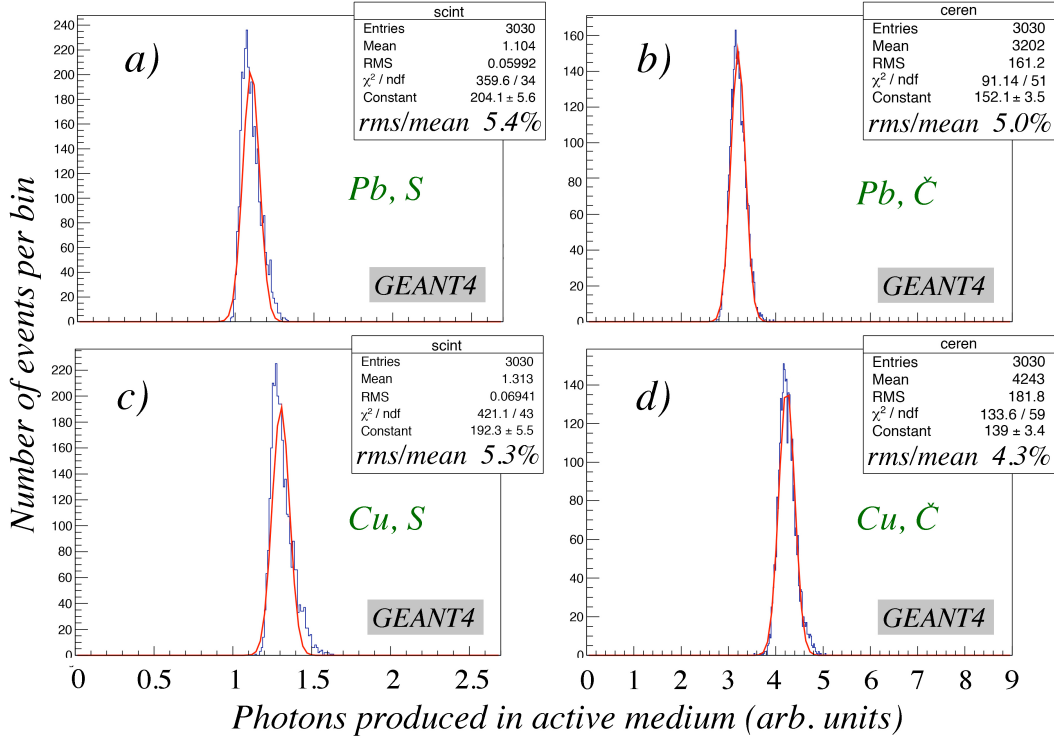

Fig. 9. Comparison of the response functions to 40 GeV electrons for the scintillator (a, c) and Čerenkov (b, d) channels in the lead (top row) and copper (bottom row) calorimeter structures. The angle of incidence (θ, ϕ) in these GEANT4 simulations was $(1.0^\circ, 1.0^\circ)$ in lead and $(0.4^\circ, 0.4^\circ)$ in copper. These values were chosen because of the substantial differences between the quality of Gaussian fits to the scintillation and Čerenkov response functions at these angles.

316 This effect can be quantified by means of variables that measure the quality of a
 317 Gaussian fit to the data points, such as the normalized value of the χ^2 , or the ratio
 318 of the *rms* width of the signal distribution and the σ of a Gaussian fit. In Figure
 319 10, the values of these variables are plotted as a function of the azimuth angle of
 320 incidence for the scintillation and Čerenkov signals from the lead calorimeter.

321 They clearly show to what extent the Čerenkov response function is better described
 322 by a Gaussian fit than the response function measured with the scintillation signals.

323 The reason for these differences is the fact that the photons produced in the ex-
 324 tremely collimated early shower component do not contribute to the Čerenkov sig-
 325 nals. Since these photons are emitted at an angle of about 50° with the direction of
 326 the shower axis (and thus with the fibers), they fall outside the numerical aperture of
 327 the fibers. This is essentially the same reason why light produced by the ionization

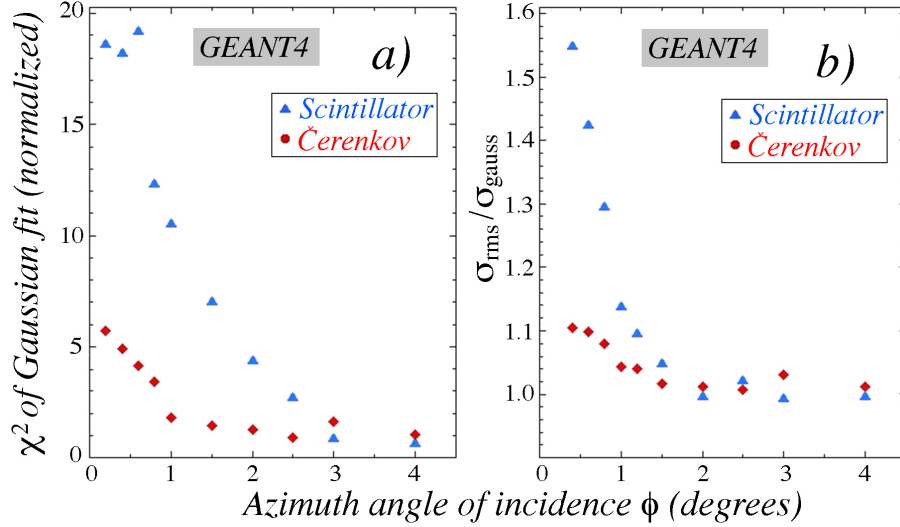

Fig. 10. The χ^2 of a Gaussian fit to the response function (a) and the ratio of the *rms* width and the σ of a Gaussian fit (b) as a function of the azimuth angle of incidence ϕ of the 40 GeV electrons. The tilt angle θ was chosen to be 1° in all these GEANT4 simulations. Results are given separately for the scintillation and Čerenkov signals in the lead structure.

328 component does not contribute to the muon Čerenkov signals (see Section 3). As
 329 a result, the Čerenkov signals have a somewhat broader radial shower profile than
 330 the scintillation signals and, therefore, the response is less dependent on the impact
 331 point of the particles.

332 Effects similar to those depicted in Figure 10 were observed for the copper struc-
 333 ture. However, since the angular dependence of the response functions is consid-
 334 erably smaller than for lead to begin with, the differences between the response
 335 functions for the two types of fibers is less spectacular than in lead.

336 4.3 Response, signal linearity and shower containment

337 In the practice of particle physics experiments, a very important characteristic of
 338 a calorimeter is the precision with which one can measure the energy of particles
 339 developing showers in it. This precision is usually assessed by measuring the energy
 340 resolution for beams of mono-energetic particles entering the detector in a precisely
 341 known point and along a precisely known line. In this subsection, we discuss some
 342 other aspects of this problem.

343 In this paper, we define the *response* of a calorimeter as the average signal per unit
 344 energy. A calorimeter is said to be *linear* if the signals it produces are proportional
 345 to the energy of the absorbed particles, in other words if the *response is constant*.
 346 We simulated the development of electrons of different energies, entering the calo-
 347 rimeter at different incident angles to investigate these issues.

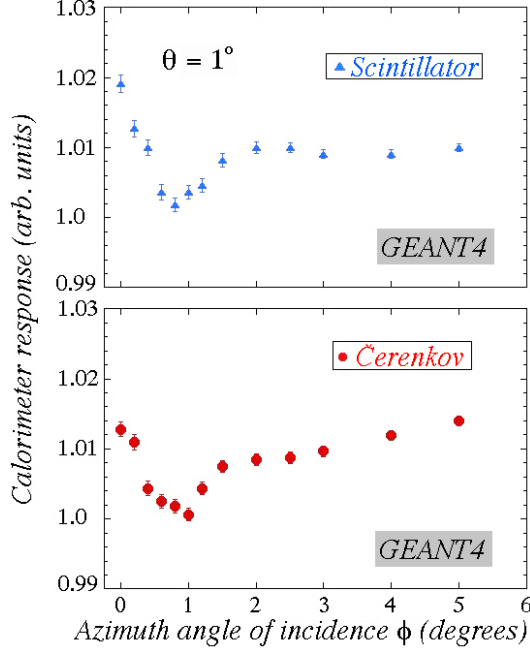

Fig. 11. Angular dependence of the electromagnetic calorimeter response for lead. Shown are the average scintillation (a) and Čerenkov (b) signals per GeV deposited energy as a function of the azimuth angle of incidence ϕ . The tilt angle was 1° in these simulations.

348 Figure 11 shows the angular dependence of the response to electrons developing
 349 showers in the lead calorimeter. These results were obtained at 40 GeV, but the
 350 results at other energies were not significantly different. The tilt angle θ was chosen
 351 to be 1° in these simulations, and that did affect the results. The dip at $\phi = 1^\circ$
 352 is a consequence of the fiber arrangement in the simulated structure. As can be
 353 seen in Figure 2c, particles entering the detector at angles $\phi = \theta$ (e.g., $1^\circ, 1^\circ$) can
 354 travel through a very narrow corridor without encountering any fiber. We verified
 355 that this effect also occurs for other geometries in which the angles of incidence
 356 in the horizontal and vertical planes were the same ($\phi = \theta$). In each case, the ϕ
 357 dependence of the response exhibited a $\sim 1\%$ dip in the vicinity of the tilt angle
 358 (θ). No such effects were observed at any other angle of incidence. The increased
 359 response at $\phi = 0$ is a consequence of the impact point dependence discussed in
 360 the previous subsection (see for example Figure 7). Figure 11 shows that for angles
 361 $\phi > 1^\circ$, the response is constant to within $\pm 0.5\%$, at least for the scintillation
 362 signals. The Čerenkov response increases very slightly with the angle of incidence,
 363 by $\sim 1\%$ between $\phi = 1^\circ$ and 5° . This is a consequence of the directionality of the
 364 Čerenkov light. As the angle of incidence increases, the acceptance of light emitted
 365 by the shower particles in the fibers gradually increases, to reach a maximum at the
 366 Čerenkov angle of 51° [16].

367 The linearity of the calorimeter was determined from simulations of electrons en-
 368 tering it at an angle of $(1.0^\circ, 1.5^\circ)$, which corresponds to the orientation used in
 369 most of our beam tests. Results are shown in Figure 12, and indicate linearity to
 370 within $\pm 0.5\%$, for electrons in the energy range from 5 - 150 GeV. Experimental

Fig. 12. The linearity of the simulated (copper) calorimeter, for electrons at an incident angle of $(1.0^\circ, 1.5^\circ)$. The shaded area represents a constant response to within $\pm 0.5\%$.

371 measurements have shown that the em response of the RD52 calorimeter was linear
 372 to within $\pm 1\%$ over the energy range 10 - 150 GeV [16].

373 Simulations of the energy deposit profile made it possible to determine the energy
 374 fraction contained in one of our RD52 calorimeter towers or modules (see Figures
 375 1,2). For 100 GeV electrons, entering the detector along the fiber direction (*i.e.*, an-
 376 gles of incidence 0,0) in the geometrical center, the simulations gave a containment
 377 of 87% in one tower and 96% in one 4-tower module. These numbers are consistent
 378 with those measured experimentally (*e.g.*, 85% containment in one tower for par-
 379 ticles entering at $(1.0^\circ, 1.5^\circ)$ in a $10 \times 10 \text{ mm}^2$ squared area around the tower center
 380 [16]).

381 4.4 The em energy resolution

382 4.4.1 Angular dependence of the em energy resolution

383 The small-angle effects on the em response function discussed in subsection 4.2
 384 also have important consequences for the electromagnetic energy resolution of this
 385 type of calorimeter. This em energy resolution is affected by Poisson fluctuations
 386 in the sampled energy fraction and in the number of photoelectrons. If this were all,
 387 one would expect the resolution to be better for the scintillation signals than for the
 388 Čerenkov ones. This is because the sampling structure is exactly the same for the
 389 two types of fibers, while the light yield for the scintillation process is much larger
 390 than for the Čerenkov effect. Yet, as illustrated by Figure 9, for small incidence
 391 angles the resolution is clearly better for the Čerenkov signals, especially in the
 392 case of the copper calorimeter.

393 Figure 13 shows the em energy resolution in the lead calorimeter as a function of
 394 the azimuth angle of incidence. For angles $\phi > 2^\circ$, the resolution is better for the

Fig. 13. The dependence of the energy resolution on the azimuth angle of incidence ϕ . Results for 40 GeV electrons in the lead calorimeter structure. The tilt angle θ was 1° in these simulations.

395 scintillation signals, but for smaller angles the Čerenkov signals provide a better
 396 resolution.

397 These phenomena have the same origin as the differences observed between the
 398 Čerenkov and scintillation response functions (see Figure 10). At small angles of
 399 incidence, the scintillation response depends much more on the impact point than
 400 the Čerenkov response. This dependence on the impact point of the particles is re-
 401 sponsible for an additional contribution to the energy resolution. This contribution
 402 is in first approximation independent of the electron energy and thus leads to a con-
 403 stant term in the energy resolution. The Poisson fluctuations in the sampled energy
 404 fraction and the light yield each contribute a term that scales as $E^{-1/2}$ to the en-
 405 ergy resolution and, therefore, the effects of the impact point dependence are most
 406 prominently visible at high energy.

407 Figure 14 shows the energy resolution in the copper calorimeter for electrons at an
 408 incident angle of $(1.0^\circ, 1.5^\circ)$. The simulations were carried out for electron energies
 409 of 5 GeV and from 10 - 150 GeV in steps of 10 GeV. The results are represented
 410 by the curves drawn in Figure 14: A solid (blue) line for the scintillation signals, a
 411 dashed (red) line for the Čerenkov signals and a dotted (green) line for the sum of
 412 both signals. The figure also contains the experimental resolutions, measured with
 413 the RD52 copper calorimeter [16].

414 The Čerenkov resolution was obtained using a quantum efficiency factor of 0.11,
 415 which corresponds to a light yield of ~ 30 Čerenkov photoelectrons per GeV de-
 416 posited energy, in good agreement with measured values for this light yield [16].
 417 The figure also shows good agreement between the simulated and measured em
 418 energy resolutions, both for the scintillation and the Čerenkov signals.

Fig. 14. The measured energy resolutions for the different signals as a function of the energy for the RD52 copper calorimeter [16], together with the GEANT4 calculations. The angle of incidence was $(1.0^\circ, 1.5^\circ)$.

419 The horizontal scale in the figure has been drawn linear in $E^{-1/2}$. Therefore, if
 420 the resolution would be completely determined by Poisson fluctuations, the data
 421 would lie on a straight line through the bottom right corner. The figure shows that
 422 the scintillation data clearly deviate from such a straight line. As mentioned above,
 423 the impact point dependence contributes an energy independent term to the energy
 424 resolution, which may be estimated to be of the order of 2-3%. The Čerenkov data
 425 suggest that such a term contributes at maximum 1% to the energy resolution.

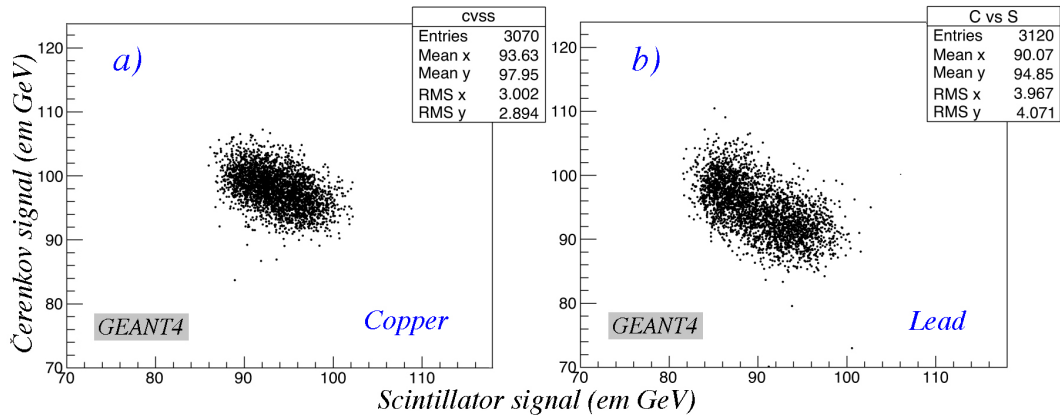

Fig. 15. Scatter plot of the Čerenkov versus the scintillation signals for 100 GeV electrons in the copper (a) and lead (b) calorimeter structures. Results from GEANT4 Monte Carlo simulations.

426 The figure also shows that the energy resolution for the sum of the scintillation
 427 and Čerenkov signals is somewhat smaller than observed in practice, although the
 428 energy dependence of this resolution is well described by the dotted (green) line.
 429 The predicted improvement in the energy resolution when combining both signals
 430 is somewhat surprising, since one would naively expect this improvement to be
 431 only due to the increased sampling fraction. Since the sampling fractions are iden-
 432 tical for the copper/scintillator and copper/Čerenkov structures, one would expect
 433 the improvement in the resolution to be at best a factor of $\sqrt{2}$. At high energies,
 434 this is about the improvement experimentally observed. Yet, the improvement in
 435 the simulated energy resolution is clearly better. We investigated the reasons for
 436 this and found that there is an anti-correlation between the simulated scintillation
 437 and Čerenkov signals, as illustrated in Figure 15. Such an anti-correlation can be
 438 understood from the fact that the signals depend, on average, on the distance be-
 439 tween the impact point and the nearest fiber that contributes to that signal, at least
 440 for the scintillation case (Figure 6). Apparently, this is also true for the Čerenkov
 441 signals and, therefore, adding both signals event by event leads to a substantial im-
 442 provement in the energy resolution, since the effects responsible for a constant term
 443 in the resolution for the individual signals cancel each other. We checked if there
 444 was any evidence for this effect in the experimental data, but did not find any. For
 445 this reason, the experimental resolutions are a bit larger than the ones predicted by
 446 GEANT4.

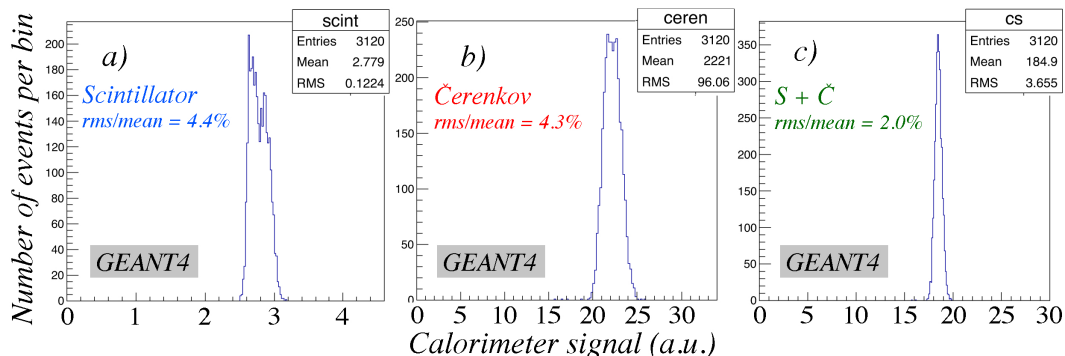

Fig. 16. The simulated response functions for 100 GeV electrons in the scintillation (a) and Čerenkov (b) channels, as well as the combined signal distribution (c), in the lead calorimeter. The electrons entered the detector at an angle ($1.0^\circ, 1.5^\circ$).

447 Not surprisingly, the predicted improvement in the energy resolution resulting from
 448 combining the two signals is even more spectacular for the lead structure. This is
 449 because the impact point dependence of the response function and, therefore, the
 450 constant term in the energy resolution is significantly larger than in the case of
 451 copper, as illustrated by the *rms* values in Figure 15. At 100 GeV, elimination of
 452 this effect by combining the two signals is predicted to improve the resolution of the
 453 combined signal by more than a factor of two, compared to that for the individual
 454 signals. This is shown in Figure 16. Also in this case, no experimental evidence for
 455 this prediction was obtained. In fact, the measured resolution for the sum of both
 456 signals was only marginally better than that for the Čerenkov signal alone [16].

457 4.4.2 Effects of an increase in the Čerenkov light yield

458 Because of the good agreement between the simulated electromagnetic energy res-
 459 olutions and the experimental data, it is also interesting to assess the improvement
 460 that might be expected if the light yield could be increased. This light yield is
 461 clearly a limiting factor for the resolution achievable in the Čerenkov channel. As
 462 indicated in the previous subsection, the simulations leading to the results shown
 463 in Figure 14 assumed a quantum efficiency for the detection of Čerenkov light of
 464 0.11.

Fig. 17. The predicted effect of an increase in the Čerenkov light yield on the em energy resolution of the copper calorimeter. See text for details.

465 Figure 17 shows the effect of increasing this factor to 0.4 on the energy resolution
 466 in the Čerenkov channel and for the combined scintillator + Čerenkov signals. One
 467 consequence is that the Čerenkov resolution becomes better than the scintillation
 468 one for all energies greater than 10 GeV. Yet, the improvement of the energy resolu-
 469 tion for the combined signals, which provides in practice by far the best resolution
 470 achievable for the detection of electromagnetic showers, is relatively modest: From
 471 4.7% to 4.0% at 10 GeV and from 1.6% to 1.4% at 100 GeV.

472 **5 Results for Hadrons**

473 In the simulations of hadron showers, the emphasis was different than for the elec-
 474 tromagnetic ones. A lack of (sufficiently detailed) experimental data was a major
 475 consideration in that respect. Our main goal was to investigate if and to what extent

476 the dual-readout method, which has been proven to work so nicely in practice, was
 477 as meritorious in the simulations. Important in that context is that the production of
 478 π^0 s and other hadrons that develop em showers be correctly treated in the simula-
 479 tion of hadronic shower development. For meaningful comparisons with the exper-
 480 imental data, a correct description of the shower containment in the limited-volume
 481 detector is important too. The very-small-angle effects on the response function and
 482 the energy resolution that affected the em calorimeter performance play almost no
 483 role for hadronic showers, where typically hundreds (or more) fibers contribute sig-
 484 nificantly to the signals. On the other hand, saturation effects in the (scintillation)
 485 light production by densely ionizing particles are of great importance for hadron
 486 showers, while these effects are insignificant for em ones.

487 5.1 Hadronic response functions

488 Experimental data on the response of dual-readout calorimeters to hadrons are
 489 available for copper [8] and lead [18]. The hadronic response functions for 60 GeV
 490 pions in lead are shown in Figure 18. The experimental data are plotted in dia-
 491 gram *a* for the scintillation signals and in diagram *b* for the Čerenkov ones. The
 492 corresponding response functions predicted by GEANT4 are given in diagrams *c*
 493 (scintillation) and *d* (Čerenkov).

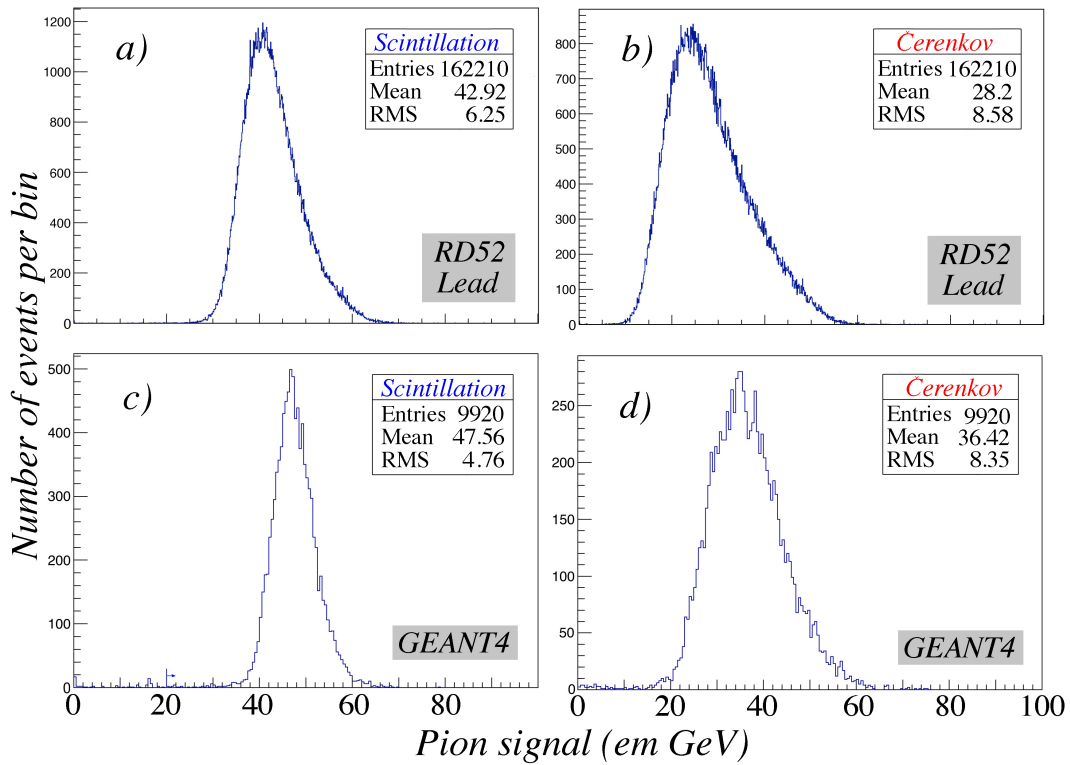

Fig. 18. The response functions for 60 GeV pions in the lead based RD52 calorimeter. Shown are the experimental data measured for the scintillation (*a*) and Čerenkov (*b*) signals, as well as the simulated response functions for these two types of signals (*c*, *d*).

494 The figure shows rather large discrepancies between the experimental data and the
 495 results of the simulations, both for the scintillation and the Čerenkov signals. In
 496 both cases, the mean value of the simulated response function was found to be
 497 quite a bit larger than the experimental value (48 vs. 43 GeV for the scintillation
 498 signals, 36 vs. 28 GeV for the Čerenkov ones). The characteristic asymmetric shape
 499 of the response function was somewhat better reproduced in the simulation of the
 500 Čerenkov signals, compared with the scintillation ones. The same was true for the
 501 *rms* widths of the signal distributions⁶.

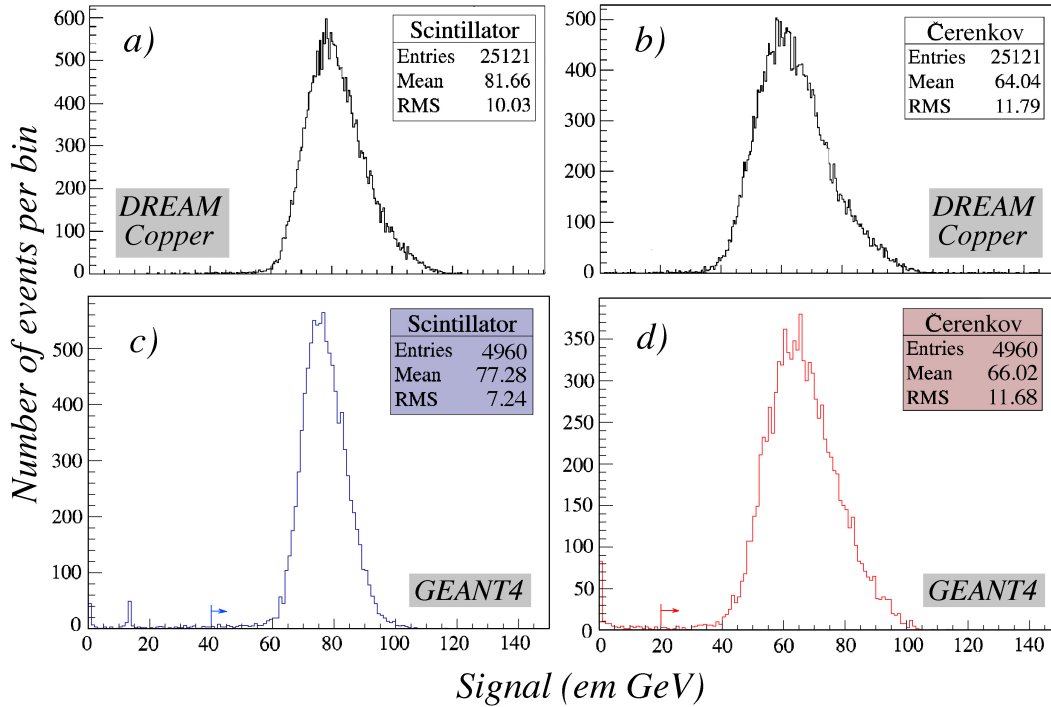

Fig. 19. The response functions for 100 GeV pions in the copper based DREAM calorimeter. Shown are the experimental data measured for the scintillation (a) and Čerenkov (b) signals [8], as well as the simulated response functions for these two types of signals (c, d).

502 The results of simulations of hadron showers in the copper based DREAM cali-
 503 orimeter were in better agreement with the experimental data. This is illustrated in
 504 Figure 19, which shows the response functions for 100 GeV pions. The experi-
 505 mental data are given in diagram a (scintillation) and in diagram b (Čerenkov). The
 506 corresponding results of the simulations are shown in diagram c (scintillation) and
 507 d (Čerenkov). The large discrepancy between the average signals in the experi-
 508 mental and simulated data for lead has largely disappeared and the shape and relative
 509 width of the simulated Čerenkov response function are in good agreement with the
 510 experimental results as well. However, the same cannot be said about the scintil-

⁶ In order to make a more meaningful comparison with the experimental data, the *rms* values of the simulated distributions were determined for signals larger than a certain cutoff value, indicated by the arrows in Figures 18 and 19. The small signals were an artifact of the (0,0) angle of incidence, and disappeared completely for angles as small as 0.2°.

511 lation response function. Just as in the lead case, this response function is more
 512 symmetric and narrow than the measured one.

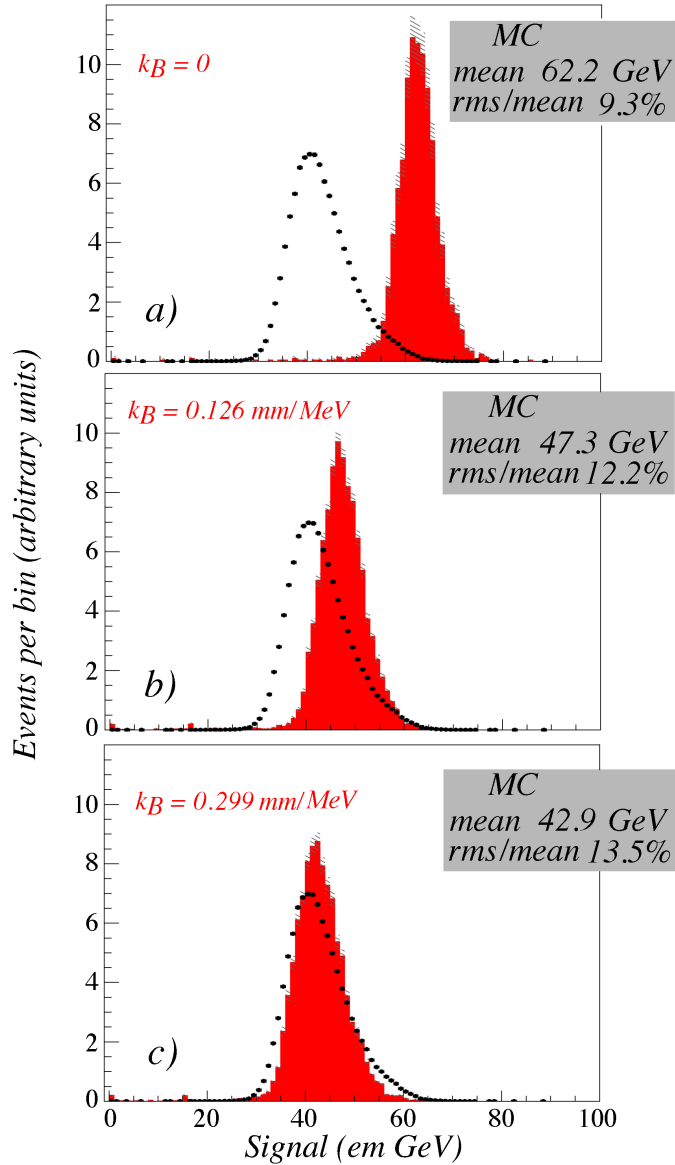

Fig. 20. Simulated scintillation signal distribution for 60 GeV pions in the RD52 lead calorimeter, without (a) or with (b, c) saturation effects for densely ionizing particles taken into account. The experimental data are shown for comparison. They are represented by the dots.

513 A major fraction of the non-em component of hadronic signals is caused by the
 514 numerous protons produced as a result of nuclear breakup reactions that take place
 515 in the shower development process. As described in Section 2.2, the signals from
 516 such protons (and from α particles and heavier nuclear aggregates) are subject to
 517 substantial saturation effects, described by Birks' constant (Equation 1). We veri-
 518 fied that the large discrepancies observed between the simulated and experimental
 519 scintillation response functions, especially in the case of lead, were not caused by

520 a wrong parameterization of these saturation effects. To that end, we simulated 60
 521 GeV pion showers with different values for Birks' constant:

- 522 • $k_B = 0$, *i.e.*, no saturation,
- 523 • $k_B = 0.126$ mm/MeV, *i.e.*, the established value for the type of scintillating fibers
 524 used in our detectors, and
- 525 • $k_B = 0.299$ mm/MeV, a value chosen because the average scintillation response
 526 equals that of the experimental distribution in that case.

527 Figure 20 shows the simulated response functions for these three values. Saturat-
 528 ion clearly affects the scintillation response function. The larger Birks' constant,
 529 the smaller the calorimeter response. The response function also becomes more
 530 asymmetric, thus better resembling the experimental data. However, as one should
 531 expect, the value of k_B barely affects the Čerenkov response function. The copper
 532 based calorimeter used exactly the same type of scintillating fibers as the lead mod-
 533 ule. Figure 19 shows that the scintillation response for this calorimeter is *smaller*
 534 than the experimental value. Increasing the k_B value would further increase this
 535 discrepancy. Therefore, we don't see a compelling reason for concluding that the
 536 literature value of the k_B value, used in our simulations, is too small.

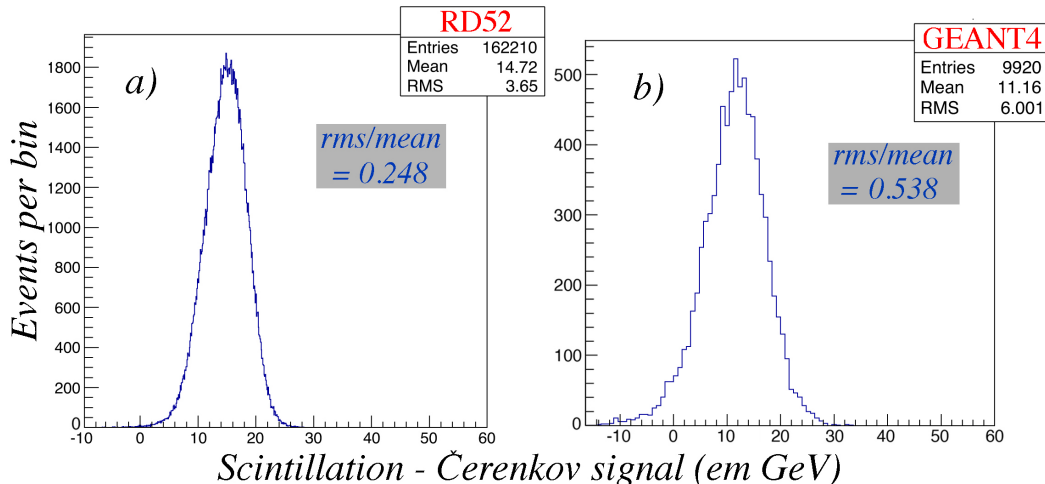

Fig. 21. Distribution of the event-by-event difference between the scintillation and Čerenkov signals for 60 GeV pions showering in the RD52 lead calorimeter. Shown are the experimental data (a) and the results of GEANT4 simulations of this process (b).

537 Another argument against an increased k_B value derives from considerations in-
 538 volving the event-to-event distribution of the *difference* between the scintillation
 539 and Čerenkov signals ($S - C$). For muons, $S - C$ reveals the contribution of the
 540 ionization component to the signals (see Figure 3). For hadron showers, $S - C$
 541 is indicative for the distribution of the contribution of the non-relativistic shower
 542 component to the signals. Figure 21 shows the $S - C$ distributions for the experi-
 543 mental and simulated lead data. The mean value of the simulated distribution (11.2
 544 GeV) is smaller than for the experimental data (14.7 GeV). Increasing the k_B value
 545 in the simulations would further increase this discrepancy. This is *a fortiori* true for

546 the signals from the copper calorimeter, where the difference between the average
 547 values of the simulated $S - C$ distribution (11.3 GeV) and the experimental data
 548 (17.6 GeV) is even larger than for lead.

549 Figure 21 also shows that the experimental distribution is more narrow and symmet-
 550 ric than the simulated one. These features indicate that the source of the observed
 551 discrepancies is the description of the “nuclear” processes, in which large numbers
 552 of non-relativistic protons and neutrons are produced, and which form the source
 553 of the *invisible energy*, *i.e.*, the nuclear binding energy which has to be provided by
 554 the showering particle and which does not contribute to any signal.

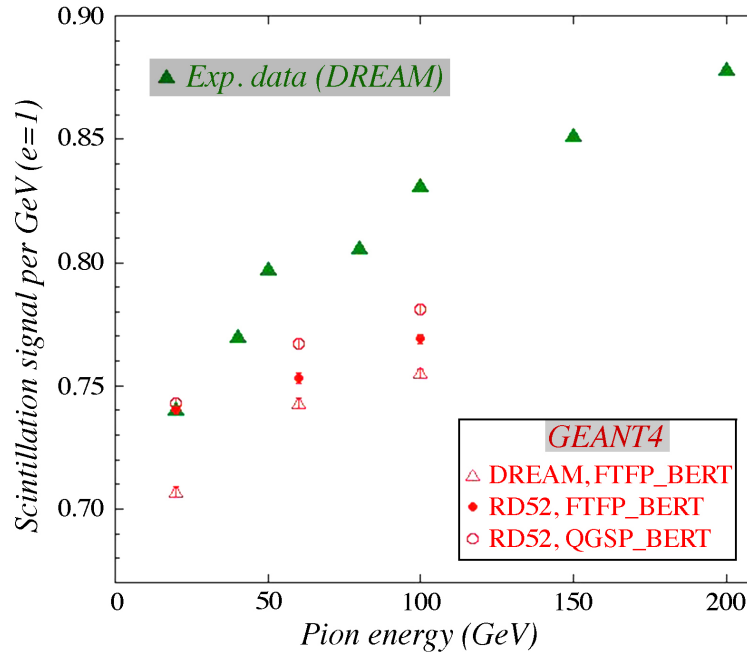

Fig. 22. The scintillation response to pions as a function of energy. The average scintillation signal per GeV is shown for the experimental data obtained with the DREAM calorimeter [8] and for various GEANT4 Monte Carlo simulations for copper (see appendix for details).

555 Additional evidence in support of this conclusion may be derived from the non-
 556 linearity of the calorimeter response to pions. Experimentally, the average scintil-
 557 lation signal per unit energy was observed to increase by about 12% between 20
 558 and 100 GeV in the DREAM calorimeter (Figure 22). However, according to the
 559 GEANT4 simulations, the increase is considerably smaller (see the appendix for
 560 numerical details). Such a discrepancy was absent for the response of the calori-
 561 meter to the Čerenkov signals. Both for the lead and copper structures, GEANT4
 562 predicts an increase of about 10% for the average signal from 60 GeV pions, com-
 563 pared to that for 20 GeV ones. This is in good agreement with the experimental
 564 observations. Since the Čerenkov signals are overwhelmingly caused by the em
 565 component of the hadron showers, *i.e.*, the π^0 component, we conclude from these
 566 comparisons that this component, and in particular its event-to-event fluctuations,
 567 are relatively well described in the simulation code.

568 5.2 The dual-readout reconstruction of the energy

569 The scintillation and Čerenkov signals simulated by GEANT4 were used to test the
 570 dual-readout method that has proven to be so successful with experimental data.

571 Figure 23 shows scatter plots in which each dot represents the scintillation and
 572 Čerenkov signals for a given event. These simulated data concern 100 (a), 60 (b)
 573 and 20 (c) GeV pions developing showers in the copper based dual-readout cali-
 574 meter. These data were used to reconstruct the energy of the showering particles,
 575 using [19,20]

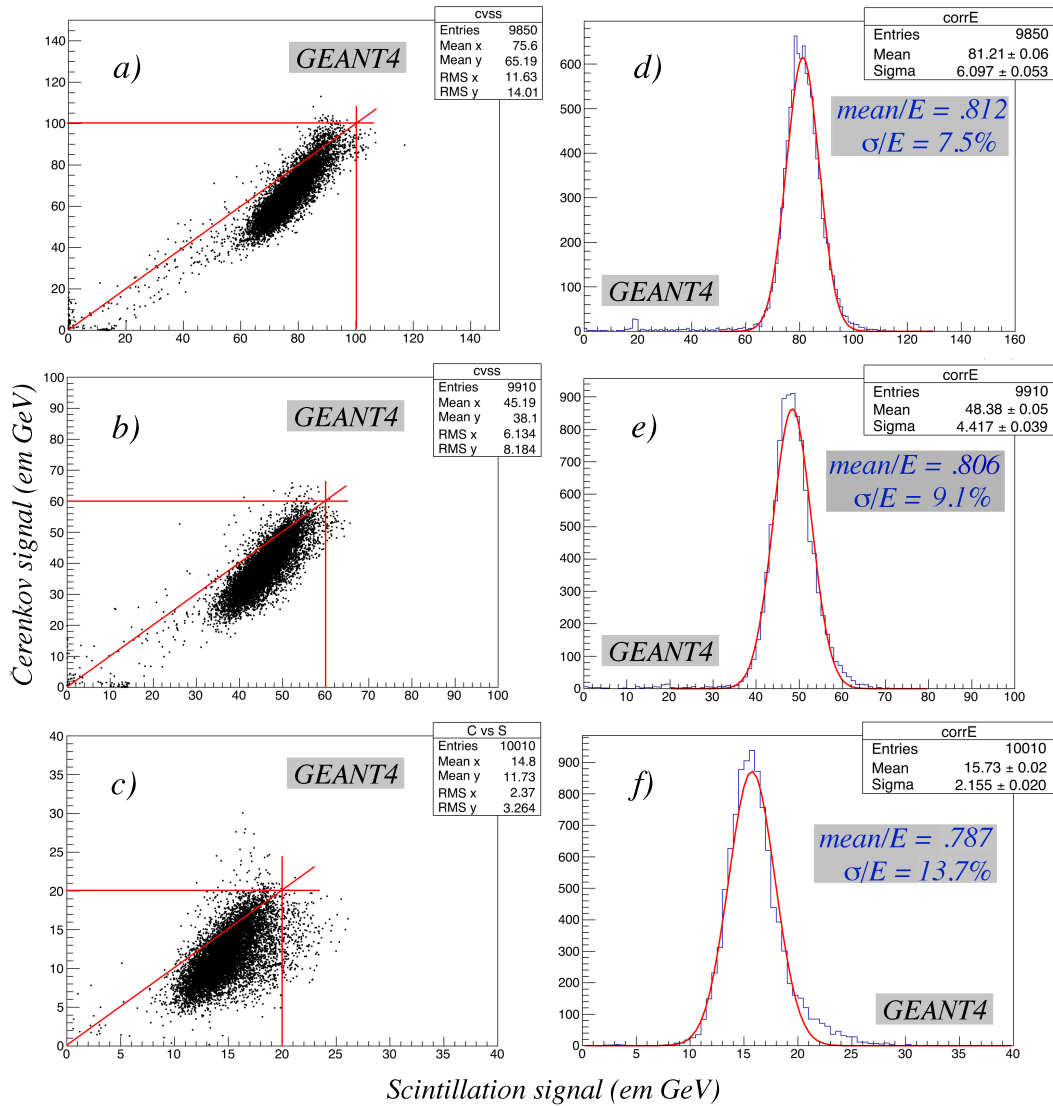

Fig. 23. Scatter plots of the Čerenkov vs. the scintillation signals for 100 GeV (a), 60 (b) and 20 GeV (c) pion showers in the copper based dual-readout fiber calorimeter, together with the reconstructed signal distributions derived from these scatter plots (d, e, f). Results from GEANT4 Monte Carlo simulations.

$$E = \frac{S - \chi C}{1 - \chi}, \quad \text{with } \chi = \frac{1 - (h/e)_S}{1 - (h/e)_C}. \quad (2)$$

576 The parameter χ is determined by the e/h values of the scintillation and Čerenkov
 577 fiber calorimeter structures. These values were measured to be 4.7 and 1.3 for the
 578 DREAM calorimeter [8], which leads to $\chi = 0.29$. This parameter value was used
 579 to reconstruct the observed energy distribution based on the simulated response
 580 functions for the scintillation and Čerenkov light. The results of this exercise are
 581 shown in Figures 23*d* (100 GeV), 23*e* (60 GeV) and 23*f* (20 GeV).

582 Especially at large energies, the distributions obtained in this way are much better
 583 described by a Gaussian function than the individual scintillation and Čerenkov
 584 response functions (see Figure 19). This confirms the experimental observations
 585 [8]. Also the energy resolutions obtained in this way are not too different from the
 586 experimental values. For example, at 100 GeV, the GEANT4 simulations for copper
 587 give a resolution of 7.5%, while the experimental value was measured to be 8.2%
 588 for pions developing showers in the calorimeter and 7.0% for pions interacting in a
 589 target just upstream of the calorimeter.

590 Yet, in one aspect, GEANT4 is clearly off, namely the fact that the average value of
 591 the E distribution is clearly too low. For fully contained showers, Equation 2 should
 592 reproduce the beam energy, and given the fact that the average side leakage is about
 593 10% in this calorimeter, one should expect an average value around 90% of the
 594 beam energy. Yet, the simulations give typically only 80% (Figure 23*d, e, f*). This is
 595 obviously a consequence of the fact that the scintillation response was typically too
 596 small and the Čerenkov response somewhat too large (Figure 19). Also, the linearity
 597 of the reconstructed energy (E) was not as good as for the experimental data. In
 598 the energy range from 20 - 100 GeV, the average E value per GeV increased by
 599 2.4% in copper. This is a consequence of the discrepancies between the measured
 600 and calculated linearity of the scintillation response discussed in Section 5.1 (see
 601 Figure 22).

602 5.3 Radial profiles and shower containment

603 One of the reasons to embark on this study was to see to what extent the recon-
 604 struction of the hadron energy by means of the dual-readout method would benefit
 605 from enlarging the existing calorimeters. To that end, the structure simulated in
 606 GEANT4 (Figure 2) was enlarged to 7×7 modules, representing a lateral cross
 607 section of $65 \times 65 \text{ cm}^2$. We used this structure to measure the radial shower pro-
 608 file, as well as the effects of enlarging the fiducial detector volume on the response
 609 functions and the reconstructed dual-readout energy.

610 Figure 24 shows the simulated radial profiles of 60 GeV pion showers developing
 611 in the copper (*a*) and lead (*b*) based fiber calorimeter structures. The energy mea-

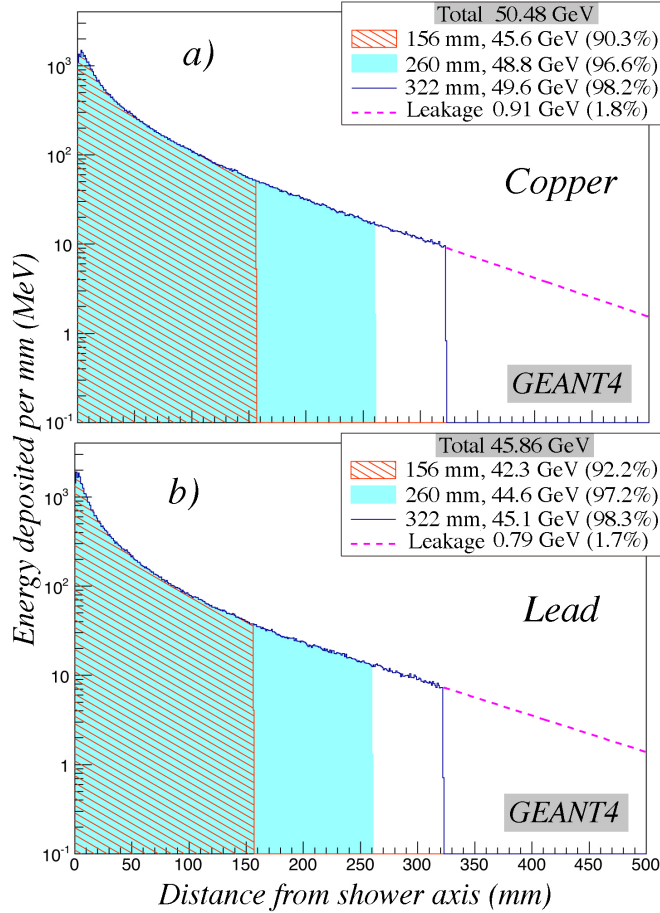

Fig. 24. Radial profiles for 60 GeV pions developing showers in the RD52 copper (a) or lead (b) based fiber calorimeters. Results from GEANT4 Monte Carlo simulations.

612 sured in thin cylindrical rings with a thickness of 1 mm is plotted as a function
 613 of their radius, *i.e.*, the distance from the shower axis. The legends show the total
 614 energy deposited in a 3×3, 5×5 and 7×7 module structure with the impact point
 615 in its center (see Figures 1, 2). They also show that the total measured energy does
 616 not equal the beam energy. This is a consequence of “invisible energy”, in the form
 617 of lost nuclear binding energy, and neutrons, neutrinos and muons escaping from
 618 the detector. These losses are substantially larger in the case of a lead absorber. If
 619 we limit the analysis to the shower particles that do contribute to the calorimeter
 620 signal, we see that the energy leaking out of the experimentally tested (3×3) ca-
 621 lorimeters amounts to 9.7% in the case of copper and 7.8% in the case of lead, in
 622 good agreement with the measured characteristics.

623 These simulation data were also used to evaluate to what extent the hadronic en-
 624 ergy resolution would improve if the calorimeter would be enlarged to a 5×5 or
 625 7×7 structure. The results, depicted in Figure 25, suggest a substantial improve-
 626 ment, especially at high energy, where the contributions of stochastic fluctuations
 627 to the energy resolution are so small that the resolution of the 3×3 calorimeter is
 628 dominated by fluctuations in shower leakage. For example, for 100 GeV pion show-

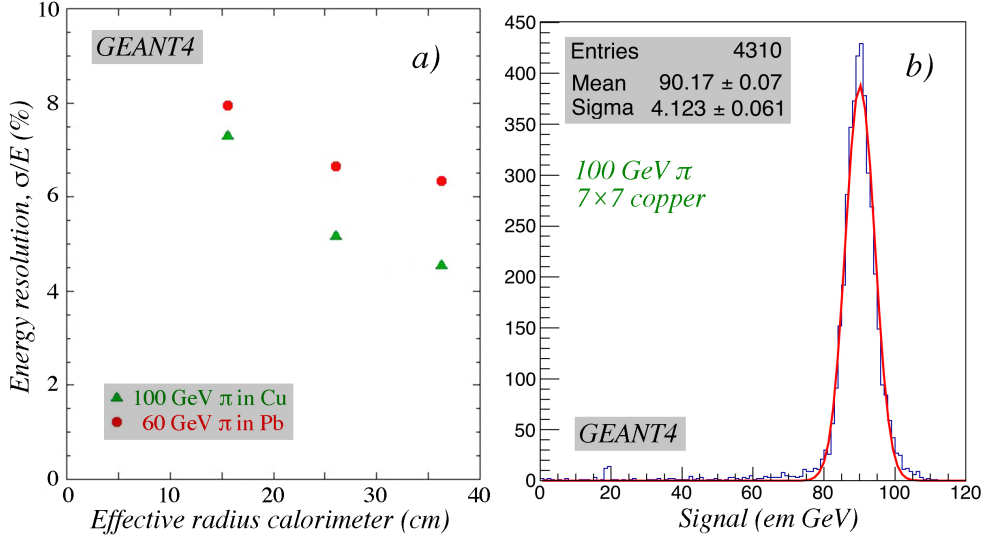

Fig. 25. The energy resolutions for 100 GeV and 60 GeV pions in dual-readout fiber calorimeters based on copper or lead absorber, respectively, as a function of the radial size of these calorimeters (a). The reconstructed energy distribution for 100 GeV pions in a 7×7 module dual-readout copper-fiber calorimeter (b). Results of GEANT4 Monte Carlo simulations.

629 ers in the copper calorimeter, the resolution is predicted to decrease from 7.5%
 630 in the 3×3 calorimeter to 5.2% in the 5×5 structure. A further increase to 7×7 mod-
 631 ules would improve this resolution to 4.5%. According to Figure 24, the average
 632 shower leakage (at 60 GeV) decreases from 9.7% (3×3) to 3.4% (5×5) to 1.8%
 633 (7×7) as a result of such an increase of the instrumented detector volume. Figure
 634 25b reconfirms the earlier observation (Figure 23) that the energy reconstruction
 635 based on the dual-readout formula (Equation 2) yields a value that is too low by
 636 $\sim 10\%$.

637 6 Discussion

638 The GEANT4 simulation package is the most widely used one in particle physics
 639 experiments, and is usually attributed great authority. However, as we have learned
 640 from the program of tests described in this paper, it clearly has its limitations, at
 641 least if one accepts that experimentally measured data represent a higher level of
 642 reality. To our knowledge, this is the first simulation of the performance of a fiber
 643 calorimeter based on the detection of Čerenkov light (or at least one of which the
 644 results are made public). The following is a summary of what we have learned from
 645 the Monte Carlo simulations of the performance of dual-readout fiber calorimeters.

- 646 • The simulation of the electromagnetic performance of the RD52 dual-readout ca-
 647 lorimeters gave in general rather good results. Especially the scintillation signals
 648 were quite well reproduced. We refer in this context to the energy dependence

649 of the muon signals (Figure 3), the energy dependence of the energy resolution
650 for electrons in the copper calorimeter (Figure 14), the shower profiles and the
651 related shower containment results (Section 4.3).

- 652 ● Some aspects of the Čerenkov signals were also quite well reproduced by the
653 simulations. For example, at small angles of incidence the large difference be-
654 tween the shape of the em response functions for the two types of signals con-
655 firmed the experimentally observed reality (Figure 9). The same is true for the
656 related fact that at high energies, the energy resolution is actually better when
657 measured in the Čerenkov channel than in the scintillation one (Figure 14).
- 658 ● Yet, when looking in more detail, we also found simulation results that were
659 clearly at variance with the measured reality. The difference between the simu-
660 lated scintillation and Čerenkov signals for muons was significantly smaller than
661 measured, while the simulated Čerenkov signals were systematically too large
662 (Figures 3,4). Another simulation result that is in disagreement with the exper-
663 imental data concerns the energy resolution achievable for the combined scin-
664 tillation + Čerenkov signals (Figures 14,16). Despite the fact that the predicted
665 resolutions for the individual signals are in good agreement with the measured
666 ones, the combined resolution is in practice not as good as suggested by the sim-
667 ulations. We have concluded that this discrepancy is the result of a perceived
668 anti-correlation between the two types of signals which is in practice *not* ob-
669 served (Figure 15). It is quite possible that at least some of these discrepancies
670 are the result of a mistreatment of the requirement that the Čerenkov light has
671 to be trapped within the numerical aperture of the fibers in order to contribute to
672 the signals.
- 673 ● One interesting, and for us somewhat unexpected, result of the simulations is
674 the advantage of copper as an absorber material, compared to lead, even for
675 electromagnetic showers. The advantage is particularly evident for particles en-
676 tering the calorimeter at very small angles with the fiber direction. In copper,
677 the degradation of the performance is already insignificant for angles as small as
678 0.2° (Figure 7), while the effects in lead are still noticeable at $2-3^\circ$ (Figure 8).
679 We have learned from these simulations that the origin of this difference is the
680 fact that the radiation length of copper is almost three times larger than for lead,
681 while the Moliere radii (which govern the radial shower development) are about
682 the same.
- 683 ● Concerning hadronic shower development, the properties of the Čerenkov com-
684 ponent are better reproduced by GEANT4 than the scintillation component. We
685 have established that the non-relativistic component of the shower development,
686 which is completely dominated by processes at the nuclear level, is rather poorly
687 described by GEANT4. Both the average size of this component, as well as its
688 event-to-event fluctuations are at variance with the experimental data. This man-
689 ifests itself in the shape of the simulated scintillation response function, which is
690 too narrow and less asymmetric than the experimentally measured one (Figures
691 18,19), and in the average contribution of the non-relativistic shower component
692 to the calorimeter signals (Figure 21). The non-linearity of the calorimeter for
693 hadronic signals is not well described for the scintillation signals (Figure 22).

694 Also in this respect, the agreement with the experimental data is better for the
695 Čerenkov signals.

- 696 • Yet, some aspects of hadronic shower development that are important for the
697 dual-readout application are in good agreement with the experimental data. As
698 examples, we mention the shape of the Čerenkov response function and the ra-
699 dial shower profiles. Attempts to use the dual-readout technique on simulated
700 shower data reasonably reproduced some of the essential characteristics and ad-
701 vantages of this method: A Gaussian response function, hadronic signal linearity
702 and improved hadronic energy resolution. The fact that the reconstructed beam
703 energy is systematically too low may be ascribed to the problems with the non-
704 relativistic shower component mentioned above.
- 705 • For these reasons, we believe that the predicted improvement in the performance
706 resulting from an increased detector size is realistic. The resolution of the instru-
707 ments tested so far was clearly dominated by leakage fluctuations. An increase
708 in the detector volume would reduce the effects of this, in which case resolutions
709 of a few percent seem to be feasible.

710 Acknowledgments

711 This study was carried out with financial support of the United States Department of
712 Energy, under contract DE-FG02-12ER41783, and by Italy's Istituto Nazionale di
713 Fisica Nucleare and Ministero dell'Istruzione, dell'Università e della Ricerca. We
714 gratefully acknowledge the facilities of and the support received from the High Per-
715 formance Computing Center at Texas Tech University, where most of the (highly
716 time consuming) simulations described in this paper were performed.

744 **Appendix - Effects of changes in the simulated geometry**

745 All simulations described in this paper were carried out for a calorimeter with a
746 simplified structure, which was not exactly the same as for the detectors that col-
747 lected the experimental data with which comparisons are being made. Especially in
748 the DREAM calorimeter, the fiber arrangement was quite different (see Figure 1c),
749 and the RD52 calorimeter contained air gaps which were not taken into account in
750 the simulations.

751 We have investigated the possible effects of these differences by means of a subset
752 of additional simulations, in which the geometry was modified such as to better de-
753 scribe the experimental reality. The results of this exercise, which can be subdivided
754 into three parts, are described in this appendix.

- 755 (1) We first investigated the possible effects of the presence of air in the RD52
756 calorimeters (see Fig. 1a,b). To that end, we have simulated a geometry such
757 as the one shown in Fig. 2c, but with each fiber surrounded by an air gap

758 with a thickness of 50 microns. The simulations with this structure were car-
 759 ried out with copper as absorber material. Since part of the copper is now
 760 replaced by air, the sampling fraction for *mips* increases from 3.9% to 4.4%.
 761 This may be compared with the sampling fraction of the RD52 copper calo-
 762 rimeter, which was 4.6% or 4.3%, depending on whether the fiber cladding
 763 is considered part of the active material or not. Other than the (trivial) effects
 764 resulting from the small increase in the sampling fraction, this change in the
 765 geometry had no significant effects on the results of the simulations. Because
 766 of the increased sampling fraction, the signals were somewhat larger and the
 767 calibration constants correspondingly smaller. The em energy resolution was
 768 also somewhat better, because of the reduced contribution of sampling fluc-
 769 tuations. However, the characteristic effects described in this paper, such as
 770 the angular dependence of the response function and the differences in that
 771 respect between the scintillation and Čerenkov signals (Figs. 6 - 13), or the
 772 anti-correlation between these two types of signals (Figs. 15,16) were not af-
 773 fected by this change in geometry.

774 Some numerical information: The e/mip value was found to be 0.83 in this
 775 “air-gap geometry”, versus 0.84 without the air-gap. The energy resolution
 776 for 40 GeV electrons (Fig. 14) improved from 4.03% to 3.43% as a result
 777 of the air-gap in the scintillation channel. The experimental RD52 value was
 778 $3.78 \pm 0.04\%$. For the Čerenkov channel, an improvement was observed from
 779 4.32% to 3.96% (experimental value $4.09 \pm 0.04\%$). For the combined S+C
 780 signals the resolution improved from 2.44% to 2.32% as a result of the air
 781 gap. The fact that the experimental value ($2.85 \pm 0.03\%$) for this sum was
 782 $\sim 20\%$ larger than both these values is a consequence of the fact that the
 783 anti-correlation between the S and C signals (Figs. 16,17 with and without the
 784 air gap) was not observed in reality. In summary, we believe that the conclu-
 785 sions drawn on the basis of the original GEANT4 simulations for electrons
 786 remain valid after these checks.

- 787 (2) To check the validity of some of our conclusions, we have implemented the
 788 DREAM geometry (see fig. 1c) in our simulation code. This code was used
 789 to simulate the response to hadrons and muons in copper, since some of the
 790 experimental data with which comparisons were made (figs. 3,4,19,22) were
 791 obtained with the DREAM calorimeter. The simulations with this DREAM
 792 geometry were carried out for 20, 60 and 100 GeV pions in copper, and also
 793 for muons with energies between 10 and 200 GeV traversing the DREAM
 794 calorimeter at 6 degrees with the fiber direction. The results obtained for the
 795 hadrons remained significantly different from the experimental data, both in
 796 terms of the response functions (fig. 19) and the hadronic signal linearity
 797 (fig. 22). For example, the non-linearity of the scintillation signals between
 798 20 and 100 GeV, which was measured to be 1.123 ± 0.010 , was found to be
 799 1.068 ± 0.010 in these simulations, and the ratio $\sigma_{\text{rms}}/\text{mean}$ for the scintilla-
 800 tion signals from 100 GeV pions, which was measured to be $(12.3 \pm 0.2)\%$
 801 turned out to be $(10.3 \pm 0.3)\%$ according to these simulations.

802 As in the RD52 geometry, the characteristics of the Cherenkov signals were

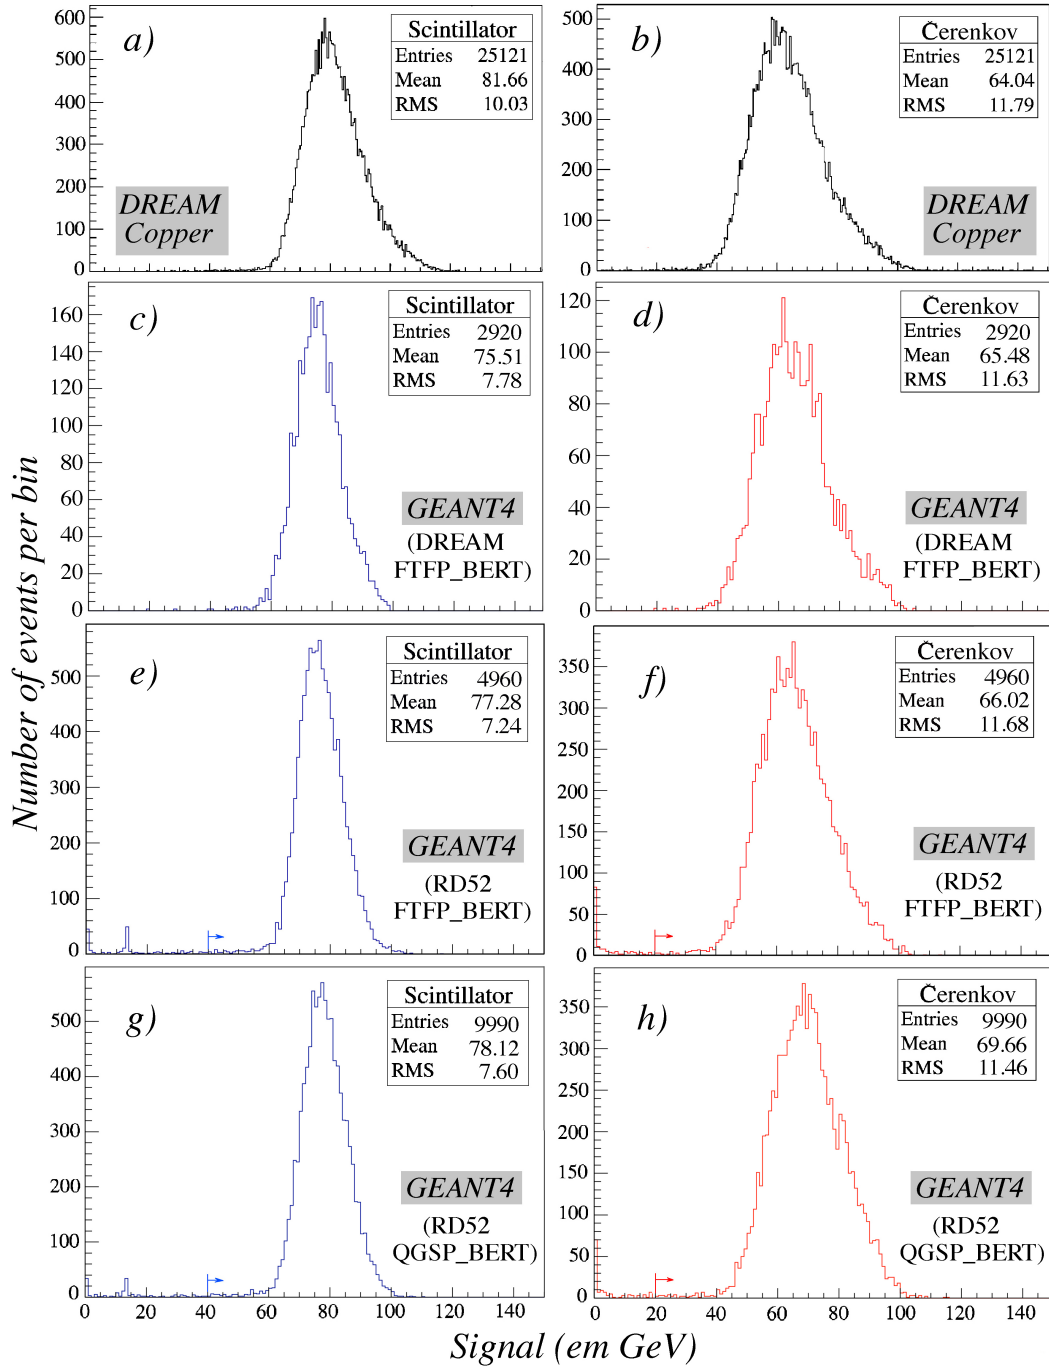

Fig. 26. The response functions for 100 GeV pions in the copper based DREAM calorimeter. Shown are the experimental data measured for the scintillation (a) and Čerenkov (b) signals [8], as well as the simulated response functions for these two types of signals in the DREAM geometry (c, d), in the RD52 geometry with the FTFP_BERT package (e, f) and in the RD52 geometry with the QGSP_BERT package (g, h).

803 better reproduced than those of the scintillation signals in the simulations with
804 the DREAM geometry. For example, the energy resolution for 100 GeV pions
805 ($\sigma_{\text{rms}}/\text{mean}$) was found to be $(17.8\pm 0.5)\%$ with the DREAM geometry, vs.
806 $(17.7\pm 0.4)\%$ with the RD52 geometry (FTFP_BERT) , while the measured
807 value was $(18.4\pm 0.3)\%$. Also, the mean value of the Cherenkov signals was
808 in better agreement with the experimental result (65.5 GeV for the DREAM
809 simulations, 64.0 GeV measured) than for the scintillation signals (75.5 GeV
810 for the DREAM simulations, 81.7 GeV measured).

811 For electron showers, where the number of fibers that contribute significantly
812 to the signals is one to two orders smaller than for hadrons, the experimen-
813 tally observed differences between the response functions for the two types
814 of signals [21] were confirmed in the simulations with the DREAM geometry
815 (As for all other simulations, 40 GeV electrons were used to determine the
816 calibration constants).

817 The GEANT4 simulations of the signals from muons (to which even fewer
818 fibers contributed) gave somewhat better agreement with the experimental
819 data when the DREAM geometry was used, even though the essential fea-
820 tures of the data were also reproduced for simulations with the RD52 geom-
821 etry. This was in particular true for the increase of the signals with the muon
822 energy and the fact that the scintillation signal was larger than the Čerenkov
823 signal, by an energy independent amount (figure 3).

- 824 (3) We have also used the original (RD52) geometry for hadron simulations with
825 a different hadron package implemented in GEANT4, QGSP_BERT. The simu-
826 lations with the QGSP_BERT package were also carried out for 20, 60 and
827 100 GeV pions in copper (RD52 geometry). The differences with the results
828 obtained with the FTFP_BERT package were minor and did not significantly
829 improve the main discrepancies between experimental and simulated perfor-
830 mance. For example, the distribution of the scintillation signal (fig. 20) was
831 still more narrow and more symmetric than in reality. The ratio $\sigma_{\text{rms}}/\text{mean}$ for
832 100 GeV pions was found to be $(9.4\pm 0.3)\%$ for FTFP_BERT, $(9.7\pm 0.3)\%$ for
833 QSGP_BERT, vs. $(12.3\pm 0.2)\%$ in the experiment. The non-linearity between
834 20 and 100 GeV (*i.e.*, the ratio between the average signal per GeV at 100 and
835 at 20 GeV, see fig. 22), which was measured to be 1.123 ± 0.010 , was simulated
836 to be 1.039 ± 0.008 with FTFP_BERT and 1.051 ± 0.008 with QGSP_BERT.
837 Figure 26 summarizes the results obtained for the different simulations of 100
838 GeV π^- showers, and the non-linearity of the hadronic scintillation signals
839 obtained with the different simulations is shown in Figure 22.

840 In summary, we believe that the conclusions drawn on the basis of the original
841 hadron simulations remain valid after these checks.

842 List of Figures

- 843 1 Front view of the tested SuperDREAM calorimeter, and the basic
844 structure of the lead (*a*) or copper (*b*) based modules. For comparison,
845 the structure of the original DREAM calorimeter is shown as well (*c*).
846 All dimensions are given in mm. 3
- 847 2 The simulated calorimeter structure. Shown are part of the front face,
848 including the $10 \times 10 \text{ mm}^2$ beam size used in the simulations (*a*), the
849 entire calorimeter module oriented at a tilt angle θ and an azimuth angle
850 ϕ with respect to the incident particle beam (*b*), and a detail of the front
851 face showing the fiber arrangement (*c*). 4
- 852 3 The average measured energy loss by muons in the DREAM copper
853 calorimeter, as a function of the muon energy. The experimentally
854 measured results are compared with the GEANT4 simulated ones.
855 The DREAM calorimeter was calibrated with 40 GeV electrons. The
856 simulations were performed for the actual (DREAM) structure of the
857 calorimeter with which the experimental data were obtained (Figure 1c). 8
- 858 4 The ratio of the average Čerenkov and scintillation signals from muons
859 traversing the calorimeter, as a function of the muon energy. The
860 experimentally measured results [9] are compared with the GEANT4
861 simulated ones. The calorimeters were calibrated with 40 GeV electrons,
862 and the simulations were performed for the actual (DREAM) structure of
863 the calorimeter with which the experimental data were obtained (Figure
864 1c). 9
- 865 5 Distribution of the energy deposited by 40 GeV electrons in the
866 scintillating fibers of the lead (*a*) and the copper (*b*) calorimeter structure.
867 The angle of incidence of the electrons (θ, ϕ) was $(1.0^\circ, 1.5^\circ)$ in these
868 GEANT4 simulations. 9
- 869 6 Distribution of the energy deposited by 40 GeV electrons in the
870 scintillating fibers of the lead (*a*) and the copper (*b*) calorimeter structure.
871 The angle of incidence of the electrons (θ, ϕ) was $(0^\circ, 0^\circ)$ in these
872 GEANT4 simulations. 11
- 873 7 Distribution of the energy deposited by 40 GeV electrons in the
874 scintillating fibers of the copper calorimeter structure. The angle of
875 incidence of the electrons (θ, ϕ) was $(0^\circ, 0^\circ)$ in diagram *a* and $(0.2^\circ, 0.2^\circ)$
876 in diagram *b*. Results from GEANT4 simulations. 12

877	8	The normalized χ^2 of a Gaussian fit (χ^2/ndf) to the response function	
878		(<i>a</i>) and the ratio of the <i>rms</i> width and the σ of a Gaussian fit (<i>b</i>) as a	
879		function of the azimuth angle of incidence ϕ of the 40 GeV electrons.	
880		The tilt angle θ was chosen to be 1° in all simulations. Results are given	
881		separately for these GEANT4 simulations of em shower development in	
882		the lead and copper/scintillating-fiber structures.	13
883	9	Comparison of the response functions to 40 GeV electrons for the	
884		scintillator (<i>a, c</i>) and Čerenkov (<i>b, d</i>) channels in the lead (top row) and	
885		copper (bottom row) calorimeter structures. The angle of incidence (θ, ϕ)	
886		in these GEANT4 simulations was $(1.0^\circ, 1.0^\circ)$ in lead and $(0.4^\circ, 0.4^\circ)$ in	
887		copper. These values were chosen because of the substantial differences	
888		between the quality of Gaussian fits to the scintillation and Čerenkov	
889		response functions at these angles.	14
890	10	The χ^2 of a Gaussian fit to the response function (<i>a</i>) and the ratio of the	
891		<i>rms</i> width and the σ of a Gaussian fit (<i>b</i>) as a function of the azimuth	
892		angle of incidence ϕ of the 40 GeV electrons. The tilt angle θ was chosen	
893		to be 1° in all these GEANT4 simulations. Results are given separately	
894		for the scintillation and Čerenkov signals in the lead structure.	15
895	11	Angular dependence of the electromagnetic calorimeter response for	
896		lead. Shown are the average scintillation (<i>a</i>) and Čerenkov (<i>b</i>) signals per	
897		GeV deposited energy as a function of the azimuth angle of incidence ϕ .	
898		The tilt angle was 1° in these simulations.	16
899	12	The linearity of the simulated (copper) calorimeter, for electrons at an	
900		incident angle of $(1.0^\circ, 1.5^\circ)$. The shaded area represents a constant	
901		response to within $\pm 0.5\%$.	17
902	13	The dependence of the energy resolution on the azimuth angle of	
903		incidence ϕ . Results for 40 GeV electrons in the lead calorimeter	
904		structure. The tilt angle θ was 1° in these simulations.	18
905	14	The measured energy resolutions for the different signals as a function	
906		of the energy for the RD52 copper calorimeter [16], together with the	
907		GEANT4 calculations. The angle of incidence was $(1.0^\circ, 1.5^\circ)$.	19
908	15	Scatter plot of the Čerenkov versus the scintillation signals for 100 GeV	
909		electrons in the copper (<i>a</i>) and lead (<i>b</i>) calorimeter structures. Results	
910		from GEANT4 Monte Carlo simulations.	19
911	16	The simulated response functions for 100 GeV electrons in the	
912		scintillation (<i>a</i>) and Čerenkov (<i>b</i>) channels, as well as the combined	
913		signal distribution (<i>c</i>), in the lead calorimeter. The electrons entered the	
914		detector at an angle $(1.0^\circ, 1.5^\circ)$.	20

915	17	The predicted effect of an increase in the Čerenkov light yield on the energy resolution of the copper calorimeter. See text for details.	21

925	20	Simulated scintillation signal distribution for 60 GeV pions in the RD52 lead calorimeter, without (<i>a</i>) or with (<i>b</i> , <i>c</i>) saturation effects for densely ionizing particles taken into account. The experimental data are shown for comparison. They are represented by the dots.	24
926			
927			
928			
929	21	Distribution of the event-by-event difference between the scintillation and Čerenkov signals for 60 GeV pions showering in the RD52 lead calorimeter. Shown are the experimental data (<i>a</i>) and the results of GEANT4 simulations of this process (<i>b</i>).	25
930			
931			
932			
933	22	The scintillation response to pions as a function of energy. The average scintillation signal per GeV is shown for the experimental data obtained with the DREAM calorimeter [8] and for various GEANT4 Monte Carlo simulations for copper (see appendix for details).	26
934			
935			
936			
937	23	Scatter plots of the Čerenkov vs. the scintillation signals for 100 GeV (<i>a</i>), 60 (<i>b</i>) and 20 GeV (<i>c</i>) pion showers in the copper based dual-readout fiber calorimeter, together with the reconstructed signal distributions derived from these scatter plots (<i>d</i> , <i>e</i> , <i>f</i>). Results from GEANT4 Monte Carlo simulations.	27
938			
939			
940			
941			
942	24	Radial profiles for 60 GeV pions developing showers in the RD52 copper (<i>a</i>) or lead (<i>b</i>) based fiber calorimeters. Results from GEANT4 Monte Carlo simulations.	29
943			
944			
945	25	The energy resolutions for 100 GeV and 60 GeV pions in dual-readout fiber calorimeters based on copper or lead absorber, respectively, as a function of the radial size of these calorimeters (<i>a</i>). The reconstructed energy distribution for 100 GeV pions in a 7×7 module dual-readout copper-fiber calorimeter (<i>b</i>). Results of GEANT4 Monte Carlo simulations.	30
946			
947			
948			
949			
950			

951 26 The response functions for 100 GeV pions in the copper based
952 DREAM calorimeter. Shown are the experimental data measured for the
953 scintillation (*a*) and Čerenkov (*b*) signals [8], as well as the simulated
954 response functions for these two types of signals in the DREAM
955 geometry (*c, d*), in the RD52 geometry with the FTFP_BERT package
956 (*e, f*) and in the RD52 geometry with the QGSP_BERT package (*g, h*). 35
